ABSTRACT

To date, few studies have explored the role of high-protein consumption in cell culture. This study examines the relationship between high-protein consumption and the occurrence of allergic reactions in cell culture. The results suggest that high-protein consumption may lead to increased production of allergens. This may be due to the presence of allergens in the medium, which can trigger an allergic reaction in cell culture. The study also suggests that the presence of allergens in the medium is not the only factor that contributes to the occurrence of allergic reactions. Other factors, such as the concentration of allergens in the medium and the duration of exposure to allergens, may also play a role in the occurrence of allergic reactions. Overall, the study highlights the importance of controlling the concentration of allergens in the medium to prevent allergic reactions in cell culture.
