ABSTRACT

Genome-wide association studies (GWAS) have identified numerous loci associated with diverse human traits. While these discoveries offer valuable insights into disease biology and inform patient care, key challenges remain. These include the disconnect between identified variants and biological mechanisms, the difficulty in detecting low-frequency or moderate-effect variants, and the inherent complexity of most human phenotypes.

To address these limitations and enhance discovery power, large sample sizes are increasingly employed through individual study expansion or meta-analysis. However, the classical single-variant approach, analyzing individual genes or variants in isolation, may not fully capture the intricate genetic architecture of complex diseases. This can be due to genetic heterogeneity or limitations associated with gene-based analysis, where power is lost due to non-effect variants within a gene or low-frequency causal variants. Consequently, traditional GWAS often lack robust mechanistic insights into the functional underpinnings of complex traits.
This thesis proposes a novel framework that integrates GWAS signals across multiple studies, leveraging summary statistics to improve association mapping and detect weak signals missed in single GWAS. The method aggregates SNP-level signals to the gene level and incorporates protein-protein interaction (PPI) networks for association mapping at gene and pathway/subnetwork levels.
We applied this framework to GWAS summary statistics from seven European bipolar disorder cohorts. The analysis identified seven genes, including a highly significant effect at the gene level for *AGT*. Additionally, a significant subnetwork was identified with Estrogen Receptor 1 (*ESR1*) as the central hub. Furthermore, the method was employed to explore the genetic overlap between suicide and psychiatric disorders in the FinnGen database. This analysis revealed disease-specific traits sharing common risk factors with suicide. Notably, several genes with small effects were identified at both the gene and subnetwork levels, highlighting the involvement of overlapping genes, pathways, and subnetworks in the underlying molecular mechanisms. Functional enrichment analysis of hub genes based on annotations from Reactome and KEGG databases revealed significant pathways, with top significant involved in signaling, nervous system development, and the immune system.
Finally, the framework was applied to investigate the genetic overlap between suicidality and subcortical brain volume. This analysis identified potentially significant genes, hub genes with small effects, along with a network of interacting genes. Enrichment analysis of the network genes revealed pathways with top significance associated with signaling, immune function, and nervous system development.

In conclusion, the method presented in this thesis provides new insights into functional and molecular mechanisms issued from a gene/subnetwork-centric approach and exhibits candidate genes for drug targets and drug re-purposing. Altogether, these findings point to important pathways and possible regulatory mechanisms that may be involved in the emergence of disorders, as well as the multi- and co-morbidities associated with them. Clinical research and an integrated strategy of additional modalities will advance individualized mechanistic understandings of these complex illnesses.

DEDICATION

This thesis is dedicated to my Lord Jesus Christ whom I trust. The one who carried me throughout this PhD journey.
To God be all the Glory!!!

Whoever is without love does not know God, for God is love
1 John 4:8

ACKNOWLEDGMENTS

One-third to half of PhD students are at risk of developing a mental disease and experiencing psychological discomfort according to some reports. Without a question, obtaining a PhD is a very challenging process, but in a welcoming and encouraging atmosphere, it can also be one of the most fulfilling and significant experiences. Being able to fully engage with a question, investigate the current quo, challenge it, formulate a plan, look for solutions, and push forward in wisdom and understanding is a fantastic grace and empowerment for both personal and professional development.

First and foremost, I am very grateful to the Lord GOD. Without Him, I wouldn't be able to embark on this PhD journey and finish well.

I am thankful to Prof Raj Ramesar for his supervision, mentorship, invaluable support, guidance, and insight that I have received throughout this PhD program. I have the privilege of receiving a lot of insightful advice from you to see beyond my comfort zone and be able to carry this project along. I have learned the concept of leadership under your mentorship, and it has expanded my vision in the field of genetics and bioinformatics in general.

I am thankful to Dr Denis Awany for his invaluable help and support. You have played a mighty role in my travail, always there to make sure about the relevance of any statistical and analytical process.

I am thankful to Prof Emile Chimusa for the privilege of introducing me to this project and laying a foundation for my bioinformatics skills.

Special thanks to my dearest wife Sandrine, for your unconditional love, support, and encouragement, always supportive and for giving me valuable advice when I was going through the darkest moment and sleepiest night for the perspective of achieving the goal. Thank you for helping me to become a better person. May God bless you abundantly.

Big thanks to Dr Faghri and Akshay, for your assistance, encouragements, support, and advice in all things concerning the lab and beyond. You have done a lot concerning the pathway for my professional career and I am so grateful to be a good listener to the multitude of your council.

I am thankful to my parents, Mr David and Mrs Jacqueline Simo; to my sisters, Aline, and Edith Laure Simo; You are all dear to my heart. Thanks to all my friends, to my brothers and sisters in the Lord Jesus Christ all around the world for your support, prayers, and encouragement. I cannot take them for granted. May God almighty bless you.

I am thankful to all my in-laws for all the support, encouragements, advices, and prayers made to GOD for me to deliver the product that we see today. May God almighty bless you.

A big thanks to all my colleagues, and staff in the Division of Human Genetics at the University of Cape Town. I genuinely appreciate the multitude of your contributions and support in various forms.

To all of you, Thank you!

But it is from Him that you are in Christ Jesus, who became to us wisdom from God[revealing his plan of salvation], and righteousness[making us acceptable to God], and sanctification[making us holy ans setting us apart for God], and redemption[providing our ransom for the penalty for sin], so then, as it is written [in scripture], "HE WHO BOASTS and GLORIES, LET HIM BOAST and GLORY IN THE LORD"

Chapter ONE: GENERAL INTRODUCTION

1. INTRODUCTION AND BACKGROUND

For more than a decade, Genome-wide Association Studies (GWAS) have successfully uncovered thousands of genetic variants in human populations susceptible to complex traits or diseases which include cancer, hypertension, schizophrenia, high blood pressure, and T2 Diabetes, amongst others. GWAS has become a powerful tool for establishing risk associations between variants and phenotypes. One of the goals of association studies is to comprehend disease aetiology and to develop viable strategies to prevent and treat diseases. As a result, many disease susceptibility loci and in some cases, unexpected disease mechanisms, have been unveiled, leading to insights into disease aetiology. GWAS signals can now be estimated, using statistical methods, both at the SNP and gene level based on the input signals and the biological features so that such loci or genes (associated with disease) may be prioritized. Until recently, GWAS studies have faced several limitations, including the inability to detect causal disease-associated markers with low or moderate risk due to limited statistical power [1,2] and the heritability of the SNPs. Additionally, there has been a lack of clear understanding regarding the interactions between genes that confer disease predisposition [2,3,4]. To overcome these shortcomings, researchers have engaged in developing statistical and computational approaches making use of various processes to improve the detection of variants associated with disease/phenotype. These included GWAS meta-analysis methods either at the SNP or gene level to increase the power of association, thereby replicating previous findings and identifying new loci [5, 6]. Others have incorporated functional information, such as protein-protein interactions (PPI) or gene expression networks, to incorporate association signals beyond a single SNP-based GWAS association [7, 8]. Generally, all of these studies focused on one phenotype at a time.

With the increasing evidence of the genetic overlap in susceptibility across different diseases and related phenotypes [9, 10, 11], unveiling the aetiological commonalities between them could reveal and contribute to a better understanding of the pathogenesis of these diseases, with potential clinical implications for disease diagnosis and management. Therefore, developing an approach that incorporates meta-analysis for the GWAS pathway will be invaluable in determining cross-phenotype associations.

1.1 EXPLORING THE GENETICS OF HUMAN DISEASES

Modern medical population genetics aims to improve the understanding of genetic mutations and potential genetic risk factors causing or contributing to human diseases. During the past century, progress toward the understanding of certain genetic diseases in individuals and families has resulted in the discovery of the Mendel law of inheritance and genetic linkage, the medical basis of disease-trait inheritance as well as the discovery of the structure and function of DNA. This has paved the way to better understand the molecular basis of many human diseases that result either from single-gene defects or of disorders due to polygenic defects. For

instance, Loddo & Romano (2015) commented that the pathogenesis of Inflammatory Bowel Disease may be triggered by genetic susceptibility, environment, intestinal microbiota, and immune system, with potential interactions as shown in **Figure 1.1**.

In this context, the international HapMap project has developed an initiative to map SNPs along the length of each human chromosome and developed a haplotype map of the human genome, describing the pattern of common human sequence variation. This initiative, discovering and mapping of millions of SNPs, has become a reference for Genome-Wide Association Studies (GWAS), is being used extensively for disease association [12]. In addition, the 1000 Genomes consortium reconstructed the genome of 2,504 individuals from 26 populations using next-generation sequencing technologies. Today, more than 85 million SNPs have been characterized as relevant for research on common diseases [13]. Several projects including the Human Genome Project [14], UK Biobank (www.ukbiobank.ac.uk), HapMap [15], H3Africa (http://www.h3africa.org/), the 1000 Genomes project [13] have become valuable database catalogues for human genetic research to map disease susceptibility and drug response. It has been estimated that the human genome contains 20,000 to 25,000 genes [16, 17]. The development of new technologies, the knowledge of the human genome sequence and the generation of markers of genetic variation have allowed investigators to associate diseases with chromosomal loci [17].

Mutations of the human DNA sequence are what cause genetic variation, and also phenotypes, including human diseases. The nature of the disease depends on the functions performed by the mutated gene [16]. In general, human genetic diseases are of two types: monogenic and polygenic. Single gene, (also called monogenic) diseases, are diseases that have a Mendelian pattern of inheritance (The Mendelian laws of inheritance, when applied to variants, stipulate that an individual carries two copies [alleles] of a given nucleotide and passes one of them at random to each of their offspring). The disease may be the result of either a single copy of the mutated allele (dominant inheritance) or both mutated copies (recessive inheritance) in an individual. Based on the pattern of inheritance, we can predict whether the mutated gene is dominant (the disorder is caused by a single copy of a mutated gene) or recessive (where both copies are mutated), autosomal (located on the autosomes [i.e. chromosomes 1 to 22] or sex-linked (on the X or Y chromosomes) [18, 16]. Inheritance and patterns of single-gene disorders which are identified via pedigree analysis of large families, with multiple affected members, have provided invaluable opportunities to understand the molecular mechanism of all hereditary diseases.

Research has shown that a large number of common diseases display a complex inheritance pattern that does not obey Mendelian inheritance patterns characteristic of single-gene disorders. These disorders are generally associated with the additive effects of multiple effects of mutations in multiple genes. With time, studies have gradually moved from monogenic diseases to polygenic diseases, which include interactions between genes, and between genes and the environment [18, 19]. An example of this complex mechanism is illustrated in **Figure 1.1.**

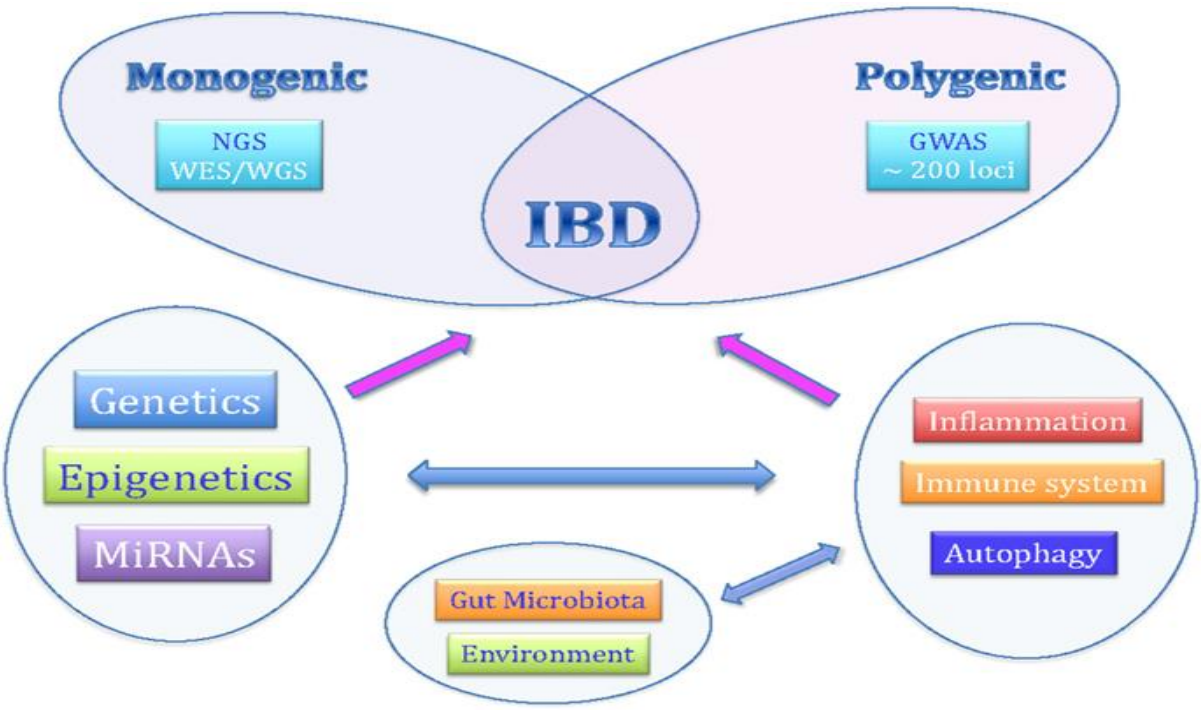

Figure 1.1 Development of IBD in most patients revealing its potential pathogenicity. Gut microbiome and environmental factors are part of the acting determinant that predispose the disease in the host. The combined effect of multiple genes added to ecological factors are elements that increase the risk of disease in most cases; this elucidates the interplay between genes and environment (blue two-sided arrows) as important elements in disease aetiology (Picture taken from Loddo & Romano (2015)).

Factors involving genetic and environmental interactions have contributed to a meaningful understanding of disease risks in general, and complex disease risk in particular. Such diseases include various Alzheimer's disease, asthma, bipolar disorder, cancers, cardiovascular diseases, coronary heart disease, diabetes, Inflammatory bowel disease, Parkinson's disease, and schizophrenia. In all such diseases, only a small fraction (between 1 to 7%) of heritability is explained by any single variant transmitted by Mendelian inheritance [19, 20]. Its manifestation depends in some part on a person's environment and lifestyle. Although genes cannot be changed, the adjustment of lifestyle and environment can prevent or delay the onset of such disorders [20, 21].

1.2 OVERVIEW OF METHODS UNDERLYING DISEASE RISK

1.2.1 LINKAGE ANALYSIS

Linkage analysis is a genetic technique used to identify the locations of genes that co-segregate with the risk of disease [22,23,24]. If a disease or trait has a genetic basis, this technique involves pinpointing the loci associated with the disease in some family members or through assessing the genetic variants each family member carries at a specific locus [23, 24]. The data for linkage analysis typically include observations of families with individuals exhibiting a

heritable disease and genotyped family members. These families can consist of parent-offspring trios, extended pedigrees, and affected sibling pairs. Evidence of linkage is established by statistically demonstrating that the disease phenotype co-segregates with a particular genetic marker within each family structure (affected and non-affected members) [23, 24]

Linkage studies have been valuable tools for detecting chromosomal locations of disease genes and identifying several genes underlying monogenic Mendelian diseases such as cystic fibrosis and Huntington disease [25, 26]. They have also been useful in detecting variants underlying familial forms of multifactorial diseases (e.g., Parkinson and Alzheimer diseases) and other hereditary syndromes like neurofibromatosis types 1 and 2 [27]. However, linkage studies are generally less effective for identifying genes associated with multifactorial diseases as a whole. One major challenge is the limited power of linkage studies in late-onset diseases with high mortality rates. Finding families with more than one affected generation can be difficult in such cases. Additionally, linkage studies are less helpful in explaining the genetic mechanisms (such as gene-gene and gene-environment interactions) underlying complex diseases [23, 28].

For Mendelian diseases, crossover events can narrow down the region of interest within the genome sufficiently to identify small intervals. However, for complex diseases, linkage analysis often identifies only large regions, typically spanning about ten centimorgans (cM). While candidate genes may exist within these linkage regions, such regions can contain dozens of genes with potential relevance to the disease. Furthermore, the prevalence of multifactorial diseases suggests that the alleles contributing to these diseases are common at both the family and population levels. To address these limitations, studies have shifted from family data to case-control data, comparing allele frequencies between affected and unaffected individuals. This approach focuses on much smaller genomic distances and pertains to disease association at both the family and population levels.

1.2.2 GENOME-WIDE ASSOCIATION STUDIES

Since its inception in the early 2000s, GWAS have become a pivotal tool for analyzing common and complex traits [1, 29, 30, 31, 32]. This approach has revolutionized human genetics, spreading globally as a method for identifying variants associated with common and complex diseases. The GWAS era emerged with the advancement of high-throughput genotyping, allowing the investigation of millions of genotypes in case-control studies. Fuelled by the common disease-common variant hypothesis, early GWAS efforts aimed to identify common variants with minor allele frequencies (MAF) above 1% (SNPs) in the general population. Despite this focus, it soon became evident that only a fraction of the heritability of most traits and diseases was explained in many studies [33, 34].

Whole-genome (WGS) and whole-exome sequencing (WES) have been considered but found to be prohibitively expensive for providing a complete picture of an individual's allelic landscape across large sample sizes. Despite decreasing sequencing costs, large-scale sequencing projects remain costly and are not typically conducted for the thousands of samples usually involved in GWAS. This led to the development and implementation of genotype imputation algorithms, which predict genotypes based on a reference panel of sequenced samples.

Within a decade, GWAS successfully identified variants contributing to various diseases and traits, including psychiatric and metabolic disorders, blood metabolite levels, and anthropometric measurements. Advances in next-generation sequencing technologies have also

highlighted the contributions of rare variants to common and complex traits. However, GWAS often suffers from inconsistent replication of variant findings [35]. Many GWAS have small or moderate sample sizes, compromising the significance of the association signals [5, 36]. For example, genetic variants underlying complex diseases like coronary artery disease and obesity typically confer small-to-moderate effects (per-allele disease odds ratios ≤ 1.2 or trait variance ≤ 0.2%) [37, 38]. These findings necessitate large sample sizes (on the order of thousands) for reliable detection of variants via GWAS.

Additionally, disease-associated SNPs often fail to explain the phenotypic variation due to the "missing heritability" problem. This issue may stem from the simultaneous testing of multiple SNPs, resulting in only a few significant SNPs while true markers remain undetected [2, 3]. The association between a single variant and a phenotype also reduces statistical power, as evidence shows multiple genetic variants across many genes are associated with phenotype-involved pathways [7, 39, 40, 41]. Moreover, pleiotropy, where one variant affects multiple phenotypes, is increasingly recognized in complex diseases. Therefore, focusing on a single phenotype may miss genetic variants associated with multiple phenotypes, hindering the understanding of genetic mechanisms influencing complex diseases [42, 43].

These challenges have led researchers to develop post-GWAS techniques to enhance GWAS findings and uncover the genetic mechanisms of various diseases and traits. One such technique is meta-analysis, a statistical method that combines datasets and aggregates estimates from independent studies to increase power and detect associations that single GWAS approaches might miss [5, 6]. Another technique is pathway analysis, which complements GWAS by tagging gene sets within the same pathway for phenotype studies [36, 44, 45].

1.2.3 POST-GWAS ERA

Scientists have successfully identified tens of thousands to millions of variants (typically SNPs) associated with the risk for complex diseases and traits through the GWAS approach [46]. However, several challenges remain in bridging the gap between understanding the biological mechanisms behind disease risk and the statistical relationships between loci and phenotypes.

The first challenge is the insufficient statistical power to detect all loci linked with the disease or trait. Most of the identified loci only account for a small portion of the total heritability, leaving the bulk of heritability still unexplained [2]. This low statistical power could be due to the presence of multiple genetic variants across many genes involved in phenotype-related pathways [7, 39, 40, 41]. The lack of coverage of genetic variants on genotyping platforms, such as rare or even private mutations, might also contribute to the missing heritability. Additionally, despite involving thousands of participants, many disease-associated variants have little to no statistical power, making them unlikely to be identified [2, 31].

Secondly, GWAS does not specify which gene or genes are affected by the causal variant (sometimes called the "target gene") nor the variant or variants at the locus causing the association (the "causal variant"). This issue arises because numerous co-inherited variants in strong linkage disequilibrium (LD) often constitute a haplotype, making it difficult to distinguish the most important disease-associated variant [47].

Thirdly, understanding the biological significance of susceptible loci and connecting them to disease causation remains challenging. Many disease-related variants are found in non-coding regions of the genome, with the majority of linked SNPs in the GWAS catalogue being in non-coding intergenic and intronic regulatory regions [48, 49]. To fully understand disease aetiology and develop effective prevention and treatment strategies, it would be ideal for GWAS results to implicate functional variants and disease pathways that can be experimentally

studied in follow-up functional studies [2, 48]. Numerous articles have highlighted additional challenges with GWAS [36, 41, 50, 51].

Given these limitations, several post-GWAS techniques have been proposed. The primary purpose of post-GWAS analysis is to use the results of genotype-phenotype associations (summary statistics) to achieve the following goals: (1) Increase the power of association to detect new functional loci that could not be detected with simple GWAS; (2) Detect novel disease susceptibility genes, gene-phenotype relationships, and biological pathway networks; (3) Use summary statistics to establish a polygenic risk score.

In the next sections, common post-GWAS approaches will be emphasised , including GWAS meta-analysis using GWAS summary statistics, pathway analysis using GWAS datasets, and network epistasis.

1.2.3.1 OVERVIEW METHODS OF GWAS META-ANALYSIS

To perform a GWAS meta-analysis, each study provides summary statistics for SNPs, which vary based on the study's purpose and the variables of interest. This information includes the genomic region of the SNP in a given human genome build, its alleles, and sometimes the frequencies of the minor alleles. Information about the SNP's association typically includes the effect size estimate, its standard error or a 95% confidence interval, and the P-value of the association between the variant and the phenotype. These statistical records are compiled into files that are smaller than the original genotype data, reducing the risk of exposing individual participant data [6, 52]. Most available information comes in the form of summary statistics. Although these statistics differ from study to study, they generally include data about the SNP and its estimated effect on the phenotype under study [5].

These summary statistics are crucial for the computational process used to generate new statistics, helping to determine whether new variants have been detected or loci have been replicated. This process involves aggregating information, estimating heterogeneity, and calculating summary effects [5, 52]. The summary effect typically includes the SNP's label being meta-analyzed, along with statistical indicators such as the overall effect size, standard error, P-values, and a 95% confidence interval.

Several GWAS meta-analysis methods have been developed, which can be grouped into three main classes: SNP-based approaches, gene-based approaches, and pathway-based approaches. These methods rely on different statistical models, such as combining P-values to produce a chi-square for association, fixed-effect (FE) models that assume genetic effects are homogeneous across studies, random-effect (RE) models that consider genetic effects to be heterogeneous, or Bayesian partition models that account for allelic heterogeneity between ethnic population groups [42, 53].

SNP-based Meta-analysis Approaches:

- These approaches analyze one genetic variant at a time using different effect models for common variants. They help address inconsistent results of a single SNP's association with a disease or trait in a given population by maximizing the power for replication.

Gene-based Meta-analysis Approaches:

- Motivated by the understanding that the genetic variability of complex traits results from the combined influence of many genetic variants within a gene,

where each variant has a small effect on the disease or trait [54]. Evidence suggests that multiple SNPs within a gene can contribute to disease risk. This approach aggregates summary information from independent causal variants within a gene or genes to enhance association signals and reduce the penalty of multiple testing [55, 56].

Pathway-based Meta-analysis Approaches:

- This novel technique integrates meta-analysis at the gene level into pathway enrichment. Pathway analysis has become a powerful tool to complement GWAS by tagging gene sets within the same pathway for studying a phenotype [36, 57]. Different genes involved in the same pathway may help identify associations that single SNPs might miss [41]. Thus, pathway-based meta-analysis is becoming a key method for evaluating the interaction effects of candidate genes within biological pathways in complex traits [58].

1.2.3.2 OVERVIEW OF GENE SET/PATHWAY ANALYSIS FROM GWAS DATASETS

Many variants underlying complex diseases only account for a portion of the causal genetic basis, with signals from causal genetic variants often hidden in the statistical noise of GWAS. While GWAS meta-analysis has retrieved signals undetected by simpler GWAS approaches, it focuses on loci associations without revealing the complete landscape of the mechanisms behind disorders. A systems approach, including pathway analysis and network modelling, can partially overcome these limitations. Network modelling helps increase statistical power to identify susceptible loci with subtle effects by using significantly associated loci derived from GWAS.

Ongoing studies have successfully uncovered the genetic architecture of various diseases and phenotypes through large-scale GWAS analysis. Evidence shows that many disorders are polygenic, involving disruptions in proteins that interact in complex ways between genes [59, 60]. Interactions between genes in a particular pathway (or gene set) can prioritize genes involved in the pathogenesis of complex diseases [36]. With the availability of biological annotations of known genes, post-GWAS methods, including meta-analysis, have shifted from single genes to gene set associations. This shift helps ascertain the interaction of predefined lists of genes involved in disease pathways and elucidates the genetic mechanisms of disorders based on existing biological and functional features [61, 56, 39].

Pathway analysis can be performed using GWAS summary statistics and can extend to rare variants, other "-omics" data, and interaction data [62]. The goal of pathway analysis is to provide insights into the biological processes by aggregating the association signals observed for a collection of SNPs into a pathway-level signal. Pathway (gene set) methods began with gene expression profiling [63] and have evolved to integrate SNP genotype data [45], sometimes combining both [64, 65, 66]. Pathway analysis is now an efficient approach to detect subtle SNP effects within the same gene set through statistical analysis of defined lists of genes with similar biological functions [64, 66]. These defined gene lists can aid in interpreting results and increase the power to detect genetic associations with the phenotype compared to individual SNPs [66, 67].

Pathway analysis involves three main steps:

1. Mapping individual SNPs to genes by genomic position and aggregating their significance to compute each gene's association with the phenotype.
2. Mapping genes into a predefined pathway database and quantifying the enrichment score of a gene set, summarizing the association scores of genes in the pathway.
3. Determining the pathway's significance based on an appropriate statistical method [56, 68].

The mapping of SNPs to genes is followed by two testing approaches:

- **Competitive approach:** Tests for over-representation of statistically significant signals of association among genes within a known biological pathway compared to genes outside the pathway, identifying enriched gene sets with a significantly higher percentage of differentially expressed (DE) genes than expected by chance [69].
- **Self-contained approach:** Performs a joint test of all gene-associated signals within the pathway to detect associations with the disease [39, 65].

Several tools have been developed for pathway analysis using GWAS, and reviews of these tools are available in peer-reviewed journals [67, 70, 62, 45, 71]. Gene set enrichment can be assessed using online pathway databases such as KEGG, Reactome, GO, WikiPathways, BioCarta, BioCyc, or NCI-NATURE [67]. The biological causes of disorders can be explored by examining changes in gene expression or mutations within a pathway.

Existing tools vary in their methods for each step and the strategies employed. Choosing the appropriate tool involves considering factors such as the null hypothesis, gene size, linkage disequilibrium between genes, and pathway size [62, 70]. Despite the usefulness of pathway analysis in describing disease mechanisms, it faces several challenges. These include poor reproducibility due to a lack of proper simulation frameworks, changes in study cohorts, different GWAS platforms, lack of imputation procedures before independent analysis, and no consensus on SNP-to-gene mapping procedures [70, 44].

Typically, hundreds of genes are involved in a pathway, and incomplete database annotations can make it difficult to reveal additional driver genes, undermining confidence in validating pathway or gene set findings in disease mechanisms. The diversity of methodologies and candidate genes used in analyses, along with the lack of standard protocols, makes replicating results challenging. There are no established guidelines for efficiently comparing pathway methodologies and tools, especially regarding the use of simulated data versus standard biological systems. Simulated datasets do not always reflect real organism events, highlighting the complexity of substantiating pathway analysis results [70].

Providing enough information for each study could help understand its strengths and weaknesses, aiding in choosing appropriate tools for pathway analysis using GWAS. Another challenge is that gene set annotation is still incomplete, causing non-annotated genes to be filtered out during analysis. To improve this process, researchers have introduced protein-protein interaction data for dense-module searching (DMS) of enriched association signals from one or multiple GWAS datasets. However, most studies using pathway analysis rely on data from a single source and a limited sample size related to one phenotype, often failing to identify new findings beyond what has already been discovered. Continuous development of pathway databases may improve the identification of candidate genes and gene sets as part of the genetic factors in disease risk.

1.2.3.3 NETWORK EPISTASIS

Increasing evidence shows that functionally related genes associated with phenotypes or traits are more likely to form networks of interacting proteins [7, 8]; such a phenomenon is called epistasis. This finding, verified for many diseases, supports the hypothesis of interaction modules, meaning protein-protein or disease-disease interactions. This interactome-based approach helps us better understand human diseases and phenotypes [72, 73]. The approach involves configuring sub-networks within the interactome, which may contain all the molecular determinants of a particular phenotype [74, 8, 75]. Combining biomedical data with networks helps evaluate disease etiologies and identify treatment markers. The most used types of interaction networks include gene regulatory networks (GRNs), metabolic networks, and protein-protein interactions (PPIs). In this thesis, the focus is mainly on PPIs.

PPI networks offer a better understanding of cellular interconnections in disease progression and could lead to identifying disease genes and pathways. This understanding could result in better drug development targets and reshape clinical practice, from identifying more precise biomarkers to disease classification, relevant to personalized medicine [7, 73]. It's important to differentiate between "pathway" and "network." Pathway analysis does not necessarily generate a network of genes but refers to a group of genes related to certain features. Conversely, a network combines all potential relationships among genes discovered for pattern prediction and disease risk [70].

The hypothesis behind the network approach is that variants not identified using single GWAS can be detected through the combined effect of multiple variants in interacting groups of genes with shared functions. This network approach is a post-GWAS procedure that assesses either interaction modules from interactive PPI networks or biological pathways using statistical information on each gene [67]. Centrality measures identify well-connected hubs (highly connected nodes) crucial for detecting subnetworks and maintaining the global network structure. These hubs reveal disease-associated genes (or driver genes) involved in complex disease mechanisms and help formulate new hypotheses about biological functions at the molecular and cellular levels.

The pattern of interconnections between nodes and edges based on important metrics has led to the introduction of scale-free networks (node degree connectivity distribution follows a power law) and small-world networks (distance between nodes grows proportionally to the logarithm of the network size) [7]. Various network-based methodologies have been applied to identify disease modules containing most disease-associated genes [76, 67]. In the recent decade, the network-based approach has shown promising progress in disease classification, disease gene prediction, and drug repurposing, especially for COVID-19. Active PPI databases are publicly accessible via web interfaces, as listed in [67]. Disease mechanisms can also be predicted using a scoring approach and genome-wide PPI network analysis.

However, network analysis should be approached with caution. Many network genes are largely incomplete, with missing nodes due to incomplete biological annotation. Identifying statistically significant subnetworks using a test statistic for each may pose problems due to the large number of subnetworks to be tested and evaluated. A large number of tests may generate many false positives or fail to identify any significant subnetworks after multiple testing corrections. Additionally, network structures may change significantly during biological or disease progression, and no example has been provided to dynamically ascertain PPIs. Despite these challenges, networks with subnetwork detection have proven valuable in addressing the

mechanisms underlying pathology and disease susceptibility. For instance, studies of network dynamics can shed light on disease-related network states [77]. Therefore, subnetworks can be considered putative driver pathways and may help unveil the functional landscape of disease mechanisms, with resulting genes acting as driver genes.

1.3 CROSS-PHENOTYPE ASSOCIATION

The recent expansion of GWAS datasets, coupled with detailed phenotypic data and epidemiological studies, has unveiled a growing number of population-based cross-phenotype associations. These associations can arise from various factors, with pleiotropy being a prominent contributor [78]. Cross-phenotype analysis offers the advantage of detecting variants with subtle effects across multiple traits or diseases. Significant GWAS findings can reveal hidden connections between seemingly unrelated conditions, prompting further investigation into shared pathways underlying these disorders. A straightforward approach to exploring cross-phenotype effects involves setting a significance threshold such that variants falling below this threshold across a set of traits are identified as cross-phenotype associations [78]. However, this method may miss truly associated variants when sample sizes are small, resulting in reduced statistical power. Consequently, several methods have been developed to combine summary information across multiple traits through meta-analysis.

Cotsapas and colleagues introduced a method called cross-phenotype meta-analysis (CPMA), which uses p-values as input and compares their distribution across all traits for a given variant to test the null hypothesis of uniform association [79]. This method is applicable to a broad range of phenotypes but is not tailored for pairwise comparisons between phenotypes. Another approach, ASSET, utilizes effect estimates of variants to identify disease subtypes within case-control data and all possible subsets of traits based on the maximum absolute Z-statistic for that variant [80]. ASSET can account for effect heterogeneity and sample overlap between traits and has successfully detected associations across different cancer risks and autoimmune disorders [81].

Zhu and colleagues developed CPASSOC, which employs two meta-analysis tests to detect cross-phenotype associations assuming homogeneous and heterogeneous effects across studies [82]. CPASSOC requires SNP information and an inter-cohort correlation matrix derived from summary statistics. This method has been applied to anthropometric traits within the GIANT consortium, revealing associations within the TOX gene that were not identified in single GWAS approaches [83]. Additional methods address trait correlations using bivariate linkage disequilibrium (LD) score regression [84, 88] or incorporate multiple testing adjustments [85]. Recently, Cichonska and colleagues proposed a metaCCA framework based on canonical correlation analysis for multivariate GWAS meta-analysis [86]. MetaCCA evaluates associations between all SNPs within the same gene and multiple phenotypes, leveraging cross-covariance matrices between genotypic SNPs and correlation structures between traits from GWAS summary statistics. However, this method assumes uniform sample sizes across traits, which may not hold in practice and can lead to underestimation of relationships for larger studies [86, 87].

While cross-phenotype meta-analysis enhances the power to detect genetic effects across multiple traits, several challenges persist. Many methods focus on SNP detection, potentially missing variants that affect only a subset of traits rather than all under study. Moreover, most meta-analysis approaches provide overall statistical evidence without identifying specific traits driving pleiotropic signals. Causal variants may exhibit varying biological impacts across different traits, complicating efforts to pinpoint pathways that best characterize pleiotropic

effects and broaden our understanding of the genetic mechanisms underlying cross-phenotype associations.

1.4 OUTLINE OF THE THESIS

This study introduces a framework for aggregating GWAS signals from individual genetic variants to gene levels, and subsequently to network and pathway levels. We applied this framework through analyses at both GWAS and meta-analysis levels using simulated and empirical datasets. Our findings underscore the potential of meta-analysis, particularly at the gene level, to reveal additional genetic associations, enhance the biological annotation of known genes, and potentially redefine disease classifications. This area of research is particularly crucial given the frequent discovery of cross-phenotype associations in GWAS studies, where the underlying aetiopathology remains unclear. Current diagnostic tools may be insufficient, and many treatment options may result in unintended side effects.

Recent studies, especially in psychiatric disorders and cancer, highlight significant comorbidity and genetic overlap. Comparative analyses across different types of cancers or psychiatric disorders reveal extensive genetic similarities, suggesting shared biological mechanisms across multiple phenotypes. This shared genetic architecture at the gene and pathway/network levels could provide valuable insights into disease classification. To address these complexities, designing gene-based and sub-network/pathway-based meta-analyses that integrate summary-level data across multiple phenotypes can capture aggregate-level pleiotropic associations. This approach leverages information from diverse population GWAS datasets and multiple variants within genes or gene sets. A deeper understanding of pleiotropy promises to offer new perspectives on disease classification, personalized medicine efforts such as drug repurposing, and the prevalence of non-responsive patient populations.

Thesis Outline

1. **Chapter 2**: Reviews existing meta-analysis methods at the variant, gene, and pathway levels, providing a mathematical description of each approach.
2. **Chapter 3**: Introduces ancMETA, a tool for performing GWAS meta-analysis at the gene and subnetwork levels using variant GWAS summary statistics and protein-protein interaction (PPI) data. This chapter demonstrates the tool's application with simulated data and real data on bipolar disorder.
3. **Chapter 4**: Investigates the genetic overlap between suicide and psychiatric phenotypes using ancMETA, analyzing summary GWAS studies from the FinnGen cohort to elucidate shared genetic contributions and molecular mechanisms underlying these disorders.
4. **Chapter 5**: Explores the genetic overlap between suicidality and subcortical brain structures using ancMETA, further probing shared genetic mechanisms.
5. **Chapter 6**: Summarizes findings from the preceding chapters and discusses future directions for GWAS meta-analysis, emphasizing insights into both single phenotype and cross-phenotype signals, with a focus on shared molecular mechanisms underlying correlated disorders.

This structured approach aims to advance our understanding of complex genetic relationships and their implications for disease management and therapeutic strategies.

Abstract

Genome-wide association studies (GWAS) have benefited greatly from enhanced high-throughput technology in recent decades. GWAS meta-analysis has become increasingly popular to highlight the genetic architecture of complex traits, informing about the replicability and variability of effect estimations across human ancestries. A wealth of GWAS meta-analysis methodologies have been developed depending on the input data and the outcome information of interest. We present a survey of current approaches from SNP to pathway-based meta-analysis by acknowledging the range of resources and methodologies in the field, and we provide a comprehensive review of different categories of Genome-Wide Meta-analysis methods employed. These methods highlight different levels at which GWAS meta-analysis may be done, including Single Nucleotide Polymorphisms, Genes and Pathways, for which we describe their framework outline. We also discuss the strengths and pitfalls of each approach and make suggestions regarding each of them.

Keywords: meta-analysis, genome-wide association studies, pathway, genes

Introduction

Genome-wide Association Studies (GWAS), which have successfully uncovered thousands of genetic variants and new genetic loci in human populations susceptible to complex traits or diseases, have begun to progressively move patients' treatment/-management to personalized medicine [1, 2]. Despite its relevant successes in the field of human-health genomics, GWAS recorded several challenges and limitations. As illustrations of these barriers, many single GWAS represents work on small or moderate sample sizes which compromise statistical power to discover a true association signal, thereby jeopardizing the relevance of a potential candidate signal [3, 4]. Moreover, it is well known that several detected disease-causing single nucleotide polymorphisms (SNPs) have small to moderate effects and their joint action cannot explain all the phenotypic variation; a phenomenon referred to as 'missing heritability' problem [5–7]. Other possible causes for the missing of true phenotype-associated markers in GWAS are thought to be due to the insufficiency of genomic coverage by markers on genotyping arrays, and the multiple testing burden from the simultaneous association testing of several SNPs [8]. The applied multiple testing correction allows a small number of SNPs to be significant, while truly associated markers not attaining significance threshold go undetected. The classical single variant approach to ascertain the association between a variant and a phenotype is limited and lowers statistical detection power given the evidence that most phenotypes result from the influence of many genetic variants in many genes and pathways [9–11]. The effect of one variant on multiple phenotypes (pleiotropy) has become an increasing phenomenon in complex diseases. Thus, the association with one single phenotype may lose the power to uncover genetic variants associated with multiple phenotypes to better understand genetic mechanisms influencing complex diseases/traits [12,13].

To overcome these shortcomings, scholars have embarked on a large-scale meta-analysis of GWAS, a statistical technique to boost statistical power to detect true associations by synthesizing and aggregating datasets and statistical estimates from two or more independent studies [3,14]. A particularly appealing merit of the method is its use of summary statistics, rather than raw genotype data. Because of this, the method has become increasingly popular in genomic analysis for complex traits, with the benefit of minimizing workload when handling genotype data from GWAS analysis while focusing on the use of published summary statistics. In addition, GWAS meta-analyses offer the potential to recover signals that a single (perhaps underpowered) study might miss [15], while at the same time addressing both 'between-study' and 'between-population' heterogeneity, thus helping uncover association signals in the presence of background heterogeneity and confounding in populations of interest [14–16]. With the advent of multiple consortia that facilitate the sharing of data between several studies, it is now feasible to perform Genome-Wide Association Meta-Analysis (GWMA).

The GWMA literature enables us to identify three categories based on the method employed, namely: (i) the SNP-based approach, (ii) the gene-based approach and (iii) the pathway-based approach. The SNP-based GWMA approach utilizes one genetic variant at a time, usually assuming fixed-effect for quantitative traits, and is mostly applied to the analysis of

common variants. Such approaches help solve inconsistent results of a single SNP association to a disease/trait in a given population, ensuring the replication of that SNP by maximizing its power. The gene-based GWMA approach is motivated by the fact that genetic variability of complex traits is the result of the influence of many genetic variants within a gene; each variant, having a small effect on the disease/trait [14]. This approach aggregates the summary information of independent causal variants within a candidate gene or genes to enrich association signals and reduces the penalty of multiple testing [17,18]. Frameworks within this category of methods include fixed as well as random effects models to ascertain associations. The fixed-effect models assume homogeneity of genetic effects in all studies, whereas random effect models treat genetic effects as heterogeneous in all studies [13,16].

The pathway-based GWMA approach is novel, in that it integrates meta-analysis at gene level into pathway enrichment. Pathway analysis has become a powerful tool to complement GWAS and enable the tagging of gene sets included in the same pathway for the study of a phenotype [4,19]. Different genes may be involved in the same pathway and may collectively contribute to identifying associations that single SNPs might have missed [11]. Owing to this, pathway-based GWMA is increasingly becoming the method of choice to evaluate the interactive effects of candidate genes comprising biological pathways in complex traits [20]. While many reviews have already described and/or rated different meta-analysis methods and software packages [3,14,21], little effort has been made to classify the different existing methods with a focus on the GWAS summary level unit information, and the statistical models employed.

We aim to describe and summarize different GWMA methodologies for SNP, gene and pathway-level meta-analyses and to assess some of the commonly used statistical tools. In doing so, we hope, to some extent, to update the review on different GWMA methods with the methodological developments in the field. We also hope to discuss the strengths and pitfalls of the various methods.

Brief historical note on GWAS meta-analysis

Meta-analysis refers to the use of statistical methods to combine and compare evidence from different independent studies. Statistical approaches to combine evidence can be dated back to the 17th century with the works developed by Blaise Pascal and Pierre di Fermat on probability theory and gambling [22]. Only recently was the term 'meta-analysis' first formulated by American statistician, Gene Glass who defined it as the analysis of analyses, and illustrated this concept in different analyses related to educational research [23]. The first application of meta-analysis was attributed to Pearson in 1904 who appraised the performance of an enteric fever vaccine across multiple clinical studies [24]. Pearson identified that the correlation between vaccination for enteritis fever and its mortality is subject to 'remarkable variations' and that the effect of enteric inoculation is largely influenced by the difference in the environment or of the treatment. He consequently recommended additional investigation using volunteers where every second participant would receive the inoculation [24]. With the availability of cheaper genotyping methods, the completion of the human genome project in 2003, and the success of the International HapMap Project, the study of genetic polymorphisms has grown rapidly to increasingly become a primary tool to locate susceptibility variants for common and complex diseases. As a result of inconsistent replications of several variants [25], researchers turned to meta-analysis to summarize results across multiple GWAS [26,27]. Since then, this technique has become a valuable approach being regularly used to discover genetic signals underlying complex traits and to replicate previously identified variants.

Popular approaches for SNP-based GWMA

In order to perform GWMA, one usually accesses a study containing SNP summary statistics, and information on the purpose of the study and the variables of interest. The summary statistics may contain labels about SNPs, odds ratios, *P*-value, effect sizes or other metrics along with their uncertainty (variance, standard error, 95% confidence interval) [15]. Most of the accessible information is in the structure of the summary statistics. Although summary statistics vary from study to study, they typically incorporate data about the SNP with its estimated effect on the phenotype under study [3]. The SNP-related information consists of the genomic region (in each build of the human genome), along with its alleles and (sometimes) the minor allele frequencies (MAFs). Information about the SNP's association frequently encompasses the effect size estimate, its standard error, or a 95% confidence interval and the *P*-value of the association between the variant and the phenotype. All these statistical records are in smaller files compared with the original genotype data which lessens the risk of uncovering individual data about study participants [14,28]. All the above-mentioned indicators are important as part of the computational process to generate new statistics using an appropriate mathematical approach that will help achieve the purpose of whether new variants along with their effect size have been detected, or loci have been replicated (confer some of these approaches in Supplementary File Section 1, available online at http://bib.oxfordjournals.org/). This process includes issues such as information aggregation, estimation of heterogeneity and summary effects [3,28]. The summary effect usually encompasses the output SNP label being meta-analysed, followed by its statistical indicators which include overall effect size, standard error, *P*-values and 95% confidence interval.

Pitfalls of SNP-specific GWMA

Despite the ongoing success of unveiling new SNPs and replicating previous SNPs in association with the disease/phenotype, the SNP-based meta-analysis approach only uses one genetic variant at a time and is mainly applied to analyse common variants. This approach does not account for the combination of genetic variants involved in the risk of the disease/phenotype as many phenotypes are polygenic. Therefore, performing an SNP-based meta-analysis may not improve the power of association when it comes to measuring the pooled effect of variants within the same biological unit (gene) involved in the biological pathway of the disease. Moreover, existing methods focused on measuring the combined effect of a SNP in the same phenotype, assuming that independence across studies tend to forget that data on several traits can be collected from the same cohort of individuals, which could result in the fact that studies may share individuals across traits. As a result, the assumption of independence across studies may not hold with the presence of overlapping individuals across studies [29,30]. In addition, the labelling and codification of SNPs may vary from data set to data set because of the so-called 'strand' issue [21,31]. Sometimes, using a small subset of SNPs, the coding of the SNPs in different studies may often cause similar effects that, in reality, look opposite, and where the diverse

Downloaded from https://academic.oup.com/bib/article/24/1/bbac600/6972298 by University of Cape Town Libraries user on 02 October 2023

features of GWMA software packages do not always produce the expectation caused by the SNP-specific effect [21]. Moreover, Begum and co-workers mentioned the choice of the genetic model used in GWAS to be included in GWMA, which constitutes a relevant challenge [21]. The GWAS summary statistics result from a particular approach, as there are different GWAS approaches for SNP phenotype disease/association. Although it is not compulsory to employ the same model in each study, the downside of this is that synthesis of all these studies might not always be possible. To our knowledge, there has not been a study of the impact of different GWAS studies on meta-analysis. The combination may cause some level of heterogeneity effects which could fail to comply with the Fixed Effect Meta-analysis (FEM) assumptions on a particular study or disease of interest [21].

Databases and software packages

Early studies on GWMA were based on multiple SNP-based GWAS summary statistics. To increase power, and ensure the replication of findings, researchers have embarked on extensive data collection. As a result, large international consortia and various databases have been formed (see Table 1) with the purpose of combining their data into meta-analyses, generally with tens of thousands of samples, and to validate the significant sets of variants found using the usual GWAS approaches. Various packages have been introduced under prior assumptions to perform GWAS SNP-specific meta-analysis (Table 2). For instance, Willer and colleagues [32] developed METAL, a two-stage meta-analysis which consists of (i) computing a weighted Z-score based on the sample size, effect size and *P*-value observed in each study, indicating how an allele is associated with lower or higher disease risk/quantitative trait levels, and (ii) generating a weighted effect size estimate based on their study-specific standard error [32]. Another useful package is MetABEL, a component of GenABEL, which applies a fixed effects model like METAL, and visualizes the results. PLINK also, an open-source package, can perform either fixed or random effect meta-analysis. GWAMA is another package which performs meta-analysis correcting for population structure within each study and potential variants between studies. GWAMA applies two measures of heterogeneity of allelic effects between studies and presents the option to perform random-effects meta-analysis in the presence of heterogeneity [33]. METASOFT has been proposed by Han and Eskin for the binary effect assumption and proposed optimal tests to detect whether some studies have an effect or not and to identify the association in the presence of heterogeneity [34]. As mentioned in the previous section, MANTRA and TransMeta have been introduced for the meta-analysis of results from multi-ethnic studies, modelling the genetic effect heterogeneity across diverse populations [16,35]. This model assumes genetic distance to be the correlation structure across ancestry groups with genetic effects taken as random variables. TransMeta achieves robust power using adaptive variance components regardless of the degree of genetic effect heterogeneity [35]. Recently, Turley and colleagues developed a tool called MAMA [36] which perform GWAS meta-analysis from distinct ancestry cohorts and produce summary statistics for each population. This tool has the advantage to account for either one or multiple phenotype.

With the increasing sample sizes and availability of variant summary statistics, GWMA has been proposed as a way forward to palliate the lack of replication of causal variants observed in GWAS, and also as a means to discover new loci that could not be identified using simple GWAS approach. Existing meta-analysis packages have emerged to increase the power of association and to detect new loci that single marker GWAS could not have detected.

Popular approaches for Gene-Specific GWMA

Over the past decades, advanced high-throughput technologies have continuously contributed to expanding GWAS. However, detecting genetic variants that have low disease risk still poses a challenge. Because single SNPs, alone, might not be responsible for a complex trait/phenotype, designing a meta-analysis approach that combines the effect of various SNPs within genes, or genes within pathways, from multiple independent population GWAS may help identify associations with small effect sizes and increase the association power.

Most of the statistical methods used in meta-analysis for GWAS focused on single genetic variant approaches by using one genetic variant at a time. These approaches do not fully account for the role of differential gene expression patterns across different tissues [44]. Small sample sizes lower the power of detection of signals of single markers due to differing patterns of linkage disequilibrium [45]. Moreover, current approaches have a lower power to detect true signals from variants with weak effects. There is evidence that multiple variants with low effect sizes, or rare variants within a region, can influence one or several traits at a time. Classical low-frequency, single-variant-based association tests, with modest effects, or rare variants, are underpowered even with the presence of large sample sizes [14,45]. Furthermore, due to poor statistical power, SNP-based analyses often ignore uncommon variations, whereas gene-based analysis may combine data from both common and rare variants and hence capture more genomic diversity than SNP-based analyses. In an attempt to strengthen and replicate signals accounting for weak effects at a time, gene-based or region-based approaches that handle multiple variants are more impactful [46]. In this regard, aggregation techniques of rare variants or low-effect variants within genes to generate score-type statistics are more valuable and efficient, particularly for binary traits [45].

Aggregation tests to detect signals of association

Gene-level association testing with rare or low-effect variants within genes has recently become a means of ascertaining gene associations with phenotypes of interest. The customary approach consists of combining information from several variants within a gene to improve association signals and to reduce the penalty of multiple testing in a linear regression framework. The most straightforward and common methodology is the burden test (or collapsing test) which computes the burden score for each set of variants in a gene for each study sample, using either a cohort allelic sums test (CAST), with binary value [47], or a weighted sum of allele counts in the region, with weight dependent on MAFs [48]. Another form of burden test is the Combined Multivariate and Collapsing test, wherein CAST is performed after having divided SNPs into subgroups according to their MAFs [49].

An alternative set of methods of aggregation is the variant threshold (VT) method which aggregates the variants within a gene in which the MAFs are under a certain threshold and minimizes the *P*-value over the observed MAF thresholds [50,51]. Other methods include the variance-component tests, to detect association of SNPs within a gene with opposite effects such as the C-alpha test [52] and the Sequence Kernel Association (SKAT) test [53]. A related test named the optimal unified SKAT-O test

Table 1. List of available summary statistics level GWAS results database

Consortium	Disease targeted	Specific features	Online download link
UK BioBank (UKBB)	Arthritis, cancer, depression, diabetes, and forms of dementia, eye disorders, Heart disease, osteoporosis, stroke,,,,	Consist of at least 500 000 participants, aged 40–69 years, from the UK general population. Sample size and statistical power are considered based on two angles: the exploration of the power profile of nested case–control studies and the likelihood number of cases that UKBB is projected to create for a range of important complex diseases	https://sites.google.com/broadinstitute.org/ukbbgwasresults/home?authuser=0 or http://geneatlas.roslin.ed.ac.uk/
Psychiatric Genomic Consortium (PGC)	Encompasses information of 11 diseases including Alzheimer's disease, attention deficit hyperactivity disorder, autism, bipolar disorder, major depressive disorder, obsessive–compulsive disorder, post-traumatic stress disorder, schizophrenia, Tourette syndrome, eating disorders, substance use disorders and all other anxiety disorders	Aim to elucidate the genetic basis of psychiatric disorders with more than 400 000 subjects with the goal to obtain GWAS data on 100 000 cases for each disorder	https://www.med.unc.edu/pgc/results-and-downloads
Enhancing Neuro Imaging Genetics Through Meta Analysis (ENIGMA)	contain group of diseases including psychiatric disorders, Infectious diseases/cancer and neurological disorders and brain volume	Contains more than 50 000 subjects and affords increased power to detect subtle effects	http://enigma.ini.usc.edu/research/download-enigma-gwas-results/
Genetic Investigation of Anthropometric Traits (GIANT)	Encompasses anthropometric traits including body mass index (BMI), height and traits related to waist circumference (such as waist-hip ratio adjusted for BMI, or WHRadjBMI)	Contains summary statistics (effect size, direction and *P*-value) of more than 2 million genotyped and imputed SNPs and high degree of ethnic differences, incorporate results of more than 100 000 individuals	http://portals.broadinstitute.org/collaboration/giant/index.php/GIANT_consortium_data_files
Cohorts for Heart and Ageing Research in Genetic Epidemiology (CHARGE)	Provides data of 14 phenotypes collected from five different cohorts (the Age, Gene/Environment Susceptibility-Reykjavik Study, the Atherosclerosis Risk in Communities Study, the Cardiovascular Health Study, the Framingham Heart Study and the Rotterdam Study). These phenotypes encompass atrial fibrillation, blood pressure, body mass index, bone mineral density, C-reactive protein, carotid intima-media thickness, echocardiography, electrocardiographic PR and QRS interval, fasting insulin, haematocrit, pulmonary function, retinal venule diameter and stroke	Genome-wide data collected from more than 38 000 individuals and provide power calculation for continuous and binary phenotype	http://www.chargeconsortium.com/main/results
Diabetes Genetics Replication and Meta-analysis (Diagram)	Only focusses on Type 2 Diabetes (T2D) with sample from individuals of European, East Asian and South Asian descent	The database contains GWAS summary statistics and metabochip data issued from various set of studies	http://diagram-consortium.org/downloads.html
Coronary ARtery DIsease Genome wide Replication plus the Coronary Artery Disease (CARDIoGRAMplusC4D)	Targets the identification of risk loci for coronary artery disease and myocardial infarction	The data contains 60 801 cases and 123 504 controls of mixed ancestry across 48 studies (77% European; 13% South Asian; 6% East Asian) with 220 SNPs. The dataset has ample power to detect variation at odd ratio and allele frequencies level	http://www.cardiogramplusc4d.org/data-downloads/
Wellcome Trust Case Control Consortium (WTCC)	Tuberculosis, Malaria, Autoimmune thyroid disease, Type 1 and 2 diabetes, Breast cancer, Crohn's disease, Coronary heart disease, Rheumatoid arthritis, Ankylosing spondylitis, Multiple sclerosis, bipolar disorder and Hypertension, Anorexia Nervosa, HIV-1, Renal Transplant Dysfunction, Pre-Eclampsia and Primary Biliary Cirrhosis	WTCC contain samples from individuals of African descent in a study of host resistance to infectious diseases (2000 cases of tuberculosis and 2000 cases of malaria, as well as 2000 shared controls). In addition, 6 diseases including coronary artery disease, Crohn's disease, hypertension, rheumatoid arthritis, type 1 diabetes and type 2 diabetes, each with 2000 cases and shared 3000 controls. Estimation of statistical power depend on the number of studies used and the statistical method	https://www.wtccc.org.uk/ccc1/summary_stats.html

Table 1. Continued

Consortium	Disease targeted	Specific features	Online download link
Genome-Wide Repository of Associations (GRASPv2.0)	GRASP contains diverse and numerous traits/phenotypes encompassing 177 categories: quantitative traits, neurological-related phenotypes, blood-related phenotypes, cardiovascular disease and cardiovascular risk factors, cancer, inflammation, behavior-related phenotypes and more	The database contains 8.87 million SNP associations reported in 2082 studies and has a web interface for direct query	https://grasp.nhlbi.nih.gov/FullResults.aspx
LD Hub (collaborative consortium developed by institutions and consortia)	Grouped GWAS summary statistics of 173 diseases/traits from publicly available resources from individuals of European and non-European descent	the database encompasses more than 965 GWAS summary-level datasets, with a web-interface where LD score and genetic correlation can be estimated; however, no statistical power is provided	http://ldsc.broadinstitute.org/
Human Heredity and Health in Africa(H3Africa)	Focus on two set of studies: one set studied the interactions between disease-causing microbes and human hosts; another set investigated non-communicable diseases such as hypertension, stroke, heart disease, diabetes or cancer, which are all becoming more common among African populations. GWAS includes 1000 cases and 1000 controls. But some other studies may involve more than 10 000 individuals all of them from African populations	Encompasses African data from the 1000 Genomes Project and the African Genome Variation Project with slightly 2.4 million SNPs information derived from H3Africa Projects	https://h3africa.org/

[54] has been introduced to make the most significant weighted linear sum of the burden and SKAT tests. The above-mentioned tests can be extended to meta-analysis using an aggregation approach and have become the basis for the construction of several bioinformatics packages to meet the demand for gene-level associations. Some of these tests will be described in the following section.

These techniques using aggregation of rare variants within a gene or region of interest are powerful to detect association of a 'causal' gene, but with limited power [46]. Thus, appropriate methods for the meta-analysis at gene level have been introduced in order to increase the power to detect associations. In this regard, summary statistics of detected genetic variants, in a particular gene, is utilized to build a score variable that incorporates association of these variants within a gene or genes for a particular disease. Such information has the relevant implication of identifying and locating genes involved in biological pathways underlying a phenotype of interest.

Software packages

Distinctive computer programs have been fashioned for the meta-analysis of gene or regional variants via a score-statistic-based meta-analysis framework (Table 3). Such packages include MASS [18], RAREMETAL [55,56], MetaSKAT [57] and seqMeta [58]. Each package computed summary statistics (score statistics and information matrices) for each study and synthesized them to perform gene-level association tests. The pipelines for each above-mentioned packages are shown in the study carried out by Tang and co-workers [59]. Tang and Lin [59] proposed a package called PreMeta which incorporates the four meta-analysis packages and allows the consortium to synthesize incompatible file formats and non-equivalent summary statistics outputs from these packages. PreMeta proposes different transformation techniques aimed at achieving normality and reduction of type I errors [59,60]. This facilitates the incorporation of summary statistics across different studies disregarding the need to perform the analysis using each software independently. Several limitations were identified in the MetaSKAT package among other uncontrolled type I error rates in the simulation results. Also, MetaSKAT does not report which cohort is highly associated with a phenotype while detecting a specific gene cohort [61]. In an attempt to solve the limitations of MetaSKAT, Ka and colleagues proposed a Meta Quadratic Test (Meta-Qtest) [61], a meta-analysis method based on the extension of the Quadratic tests [44]. This method accounts for the relationship of multiple variants in the gene/region, keeping the original statistical model structure of the QTest, and the process of deriving the statistics. Such an approach constitutes a great advantage to maximize the test statistics [61]. Besides the above popular packages, Fan and colleagues [30] developed an approach making use of Generalized Functional Linear Models (GFLMs). GFLMs are fixed models in which association between a complex dichotomous trait and multiple genetic variants is tested using chi-squared-distributed Rao's efficient score test and likelihood-ratio test (LRT) statistics [30]. Fan and colleagues showed that Rao's score test statistics have similar or slightly lower power than MetaSKAT. In addition, the LRT statistics perform accurate type I error rates for FEM, may inflate type I error rates for REM owing to a large number of degrees of freedom and have similar or slightly higher power than Rao's efficient score test statistics [30]. Another tool called MAGA was proposed to perform gene-level meta-analysis using single variant summary statistics and correlation matrix from the available reference panel [62]. MAGA can be used as an alternative in the case when score statistics and information matrices cannot be obtained. Nevertheless, the method is limited to single ancestral populations and does not perform well in the presence of a few studies coming from different ancestral populations with few reference panels [62].

Pathway-level meta-analysis

Ongoing studies successfully uncover the genetic architecture of several diseases/phenotypes via the analysis of large GWAS. Evidence shows that many disorders are 'polygenic' (many genetic loci contribute to risk), as reflected by disruptions in proteins that participate and involve complex interactions between genes [63,64]. Interaction between genes involved in a particular pathway (or gene set) may prioritize genes underlying the pathogenesis of complex disease risk [4]. With the availability of biological annotation of known genes, post-GWAS methods, which include meta-analysis, has shifted from single genes to gene set associations in order to ascertain the interaction of predefined lists of genes that can be involved in a pathway of disease risk and to elucidate the genetic mechanisms of the disorders, according to existing biological and functional features [65–67]. Pathway (gene set) methods, which were first initiated using gene expression profiles [67], have gradually evolved by integrating SNP genotypes [68] and, sometimes, a combination of the two [69–71]. Pathway analysis has become an efficient approach which offers the potential to detect subtle SNP effects of the same gene set, via statistical analysis of a defined list of genes having similar or related to a similar biological function [70,71]. The evidence of these defined lists of genes having similar biological and functional features may aid investigators in the interpretation of results. In addition, pathway analysis offers the potential to increase the power to detect genetic associations of the phenotype with the gene set, as compared with the power to detect association with an individual SNP [71,72]. Pathway analysis encompasses three main steps: (i) individual SNPs are mapped to genes (by genomic position) and their significance is aggregated to compute the association of each gene with the phenotype; (ii) map the gene into a predefined pathway database and quantify the enrichment score of a gene set, which summarizes association scores of genes in the pathway and (iii) elucidate the significance of the pathway based on appropriate statistical methods [65,73]. The mapping of SNPs to genes is followed by the choice of two testing approaches: (i) either for over-representation of statistically significant signals of association among genes (also called gene set enrichment) within a known biological pathway compared with the number of such signals among genes outside the pathway. This technique is labelled the 'competitive' approach. An enriched gene set is defined as a set that has a significantly higher percentage of differentially expressed genes than would be expected by chance [74]; (ii) alternatively perform a joint test of all gene-associated signals within the pathway for detecting association with the disease. Such a technique is labelled the 'self-contained' technique [69,75]. A variety of pathway databases as well as pathway analysis methods from a collection of GWAS summary statistics to detect the significance of a biological pathway have been proposed and reviewed [72,76]. These methods have shown some level of success by improving the power in pinpointing gene set activities, which uncover the genetic mechanism of certain phenotypes. However, albeit this level of success, various pathway analysis techniques often fail to provide new findings beyond what has already been uncovered due to the limited sample sizes of many current studies. As a result, combining multiple studies by integrating either the same type of SNP summary data or gene expression profiles across participating studies offers the possibility to increase power and reproducibility and could provide opportunities for detecting novel pathway associations [73].

Meta-analysis for pathway enrichment

The first approach highlighted in meta-analysis at the pathway level has been introduced by Shen and Tseng [65], motivated by the observation that the identified DE genes from microarray studies do not directly connect to the phenotype of interest, added to the need to improve the gene set enrichment analysis (GSEA) proposed by Subramanian *et al.* [69]. With the advantage of pathway analysis, they developed a tool which combines the statistical significance across studies at gene level before moving to pathway analysis or at the pathway level after pathway analysis. The method includes three method frameworks denoted: (i)

Downloaded from https://academic.oup.com/bib/article/24/1/bbac600/6972298 by University of Cape Town Libraries user on 02 October 2023

MAPE at gene level ($MAPE_G$), (ii) MAPE at pathway level ($MAPE_P$) and (iii) MAPE integrated ($MAPE_I$).

Shen and Tseng [65] made an important foundational effort in developing MAPE. This model holds promise in exploring power increase in pathway association; however, MAPE methods may be subject to power loss, as they do not account for different set sizes in their permutation-based procedures, and fall short of clearly managing between-study heterogeneity. All these limitations affect the performance of MAPE methods and have led several scholars to develop alternative tools to overcome these shortcomings [77].

Integrated Bayesian model for meta-analysis of gene set enrichment

Chen and colleagues [74] proposed an integrated Bayesian framework, which models gene expression data from multiple studies and gene set information, and perform differential expression analysis, together with gene set enrichment analysis and meta-analysis. Unlike MAPE, which makes use of a sequential approach, Chen and co-workers proposed a Bayesian inference model, which jointly models gene set information and expression data from multiple studies and exhibits between-study heterogeneities for gene expression data by including non-overlapping genes [74].

One of the advantages of this approach is the integration of all the parameters in the model to perform pathway/gene set meta-analysis in parallel rather than in a sequential manner. Despite great human efforts to locate the convergence of Markov Chain Monte Carlo in the model, the use of the classification strategy makes the results relatively easy to interpret [74]. However, the model is limited to binary phenotypes making it difficult to perform gene set enrichment for complex traits.

Integrative gene set enrichment analysis

In the perspective of improving the gene set meta-analysis using gene expression statistics, Lu and colleagues proposed a method which integrates multiple independent gene-set enrichment studies sharing a common phenotype. This method allows the possibility to choose either a Fixed Effect, Random Effect meta-analysis approach or Adaptive testing approach for achieving robustness against model misspecification. This model applies to both discrete and continuous phenotypes [77]. The algorithm process includes the computation of the gene level statistics for each study taking information from the gene expression level data, followed by the overall computation of the gene level meta-analysis based on score statistic [18,60] to address between-study heterogeneity, and finally, using an appropriate database of gene sets, ascertain enrichment of the identified gene sets [77].

The model recommends the use of Adaptive testing in combining GSEA studies because of its performance in fitting multiple gene set sizes. However, the permutation procedure is much slower when the number of genes is larger [77]. The model is found to outperform the MAPE method [65] in terms of power and is able to adapt for covariates in the computational process. The method can extend its application to microarray analysis and NGS experiments in addition to other omics such as epigenomic studies in large consortia [77].

Meta-analysis with quantitative set analysis for gene expression

One of the methods introduced in gene set analysis was the quantification of gene set differential expression activities via a probability density function (PDF) rather than a *P*-value as widely used [78]. This approach labelled QuSAGE, accounts for gene–gene correlation and uses a modified PDF to generate a variance inflation factor (VIF) from the data without assuming equal variances for all the genes in each gene set [78]. Meng and colleagues [79] extended the QuSAGE approach to meta-analysis which can be summarized in three steps: (i) gene sets analysis for each study is carried out through QuSAGE whereby, through PDF, the activity of each gene is quantified. After that, all PDFs for each gene belonging to a particular gene set are synthesized using numerical convolution in a single activity. The VIF is generated accounting for gene–gene correlations assuming no equal variance for all the genes in each gene set; (ii) the model performs meta-analysis in which the PDFs of all individual studies are combined using a weighted numeric convolution algorithm in a function called 'combinePDFs' [79]. This process is preceded by a sampling of a finite number of points proportional to its weight from each continuous PDF within an interval that encompasses their ranges. The weighting factor from the combination denotes the sample size for each study; (iii) the significance of the combination is extracted from the combined PDFs and the figure of the outcome is visualized in a function called 'plotCombinedPDF' [79]. By modelling the intra- and inter-study variance this way, the method increases the power of analysis by detecting biologically appropriate gene sets that could not be identified via single studies while at the same time adjusting for variance inflation allowing it to also account for gene–gene correlations. In addition, the statistic used to describe gene set activity (PDFs) is based on the numeric convolution algorithm which fully accounts for the differences and the direction of the gene set activities. This measure provides a better accuracy estimation compared with the *P*-values or single statistics, which does not fully uncover the gene set activity [79]. However, the method ignores the heterogeneity of variance in high-throughput data and disregards the nature of gene set overlap in different gene sizes. These aspects affect gene set activities in the sense that, in the gene annotation database, several genes sets overlap as a result of genes involved in different pathways and processes [80]. This area could be an avenue for future investigations.

Meta-analysis-based summary adaptive rank truncated product

In the preceding sections, we describe methods which perform pathway-based meta-analysis using gene expression data added to their advantages and limitations. GWAS-based pathway analysis is a powerful tool to complement GWASes to detect significant gene sets that may explain the studied trait/phenotype. More recently, many GWAS-based pathway analysis has been successfully used to investigate associated pathways and to uncover the genetic mechanism of complex human traits/phenotypes [68,72,75]. Since standard marker approaches may miss genes involved in the same pathway, combining the same type of GWAS summary data across multiple contributing studies offers the possibility of bringing about novel pathway associations that might not have been discovered using a single study approach. Moreover, pathway-based meta-analysis provides the option of evaluating biological consistency across GWAS results and reduces the multiple comparison burden besetting the identification of novel loci involved in new pathways for the outcome of interest [81]. Summary adaptive rank truncated product (sARTP) is a method which takes as input GWAS SNP association results from multiple studies, added to their correlations estimated from a sample of reference panels with individual-level genotype data [81] (confer method description in Supplementary File Section 3.4, available online at http://bib.oxfordjournals.org/). Though the

Downloaded from https://academic.oup.com/bib/article/24/1/bbac600/6972298 by University of Cape Town Libraries user on 02 October 2023

model provides possibilities to identify novel pathway signals that were undetectable due to the limitation of sample size, Zhang and colleagues mentioned the importance of SNP coverage information to accurately compute a variance–covariance matrix as most of the consortia do not provide this element. Zhang demonstrated that a lack of SNP coverage information may lead to an inflated false positive rate [81]. This method provides an avenue to extend the model accounting for LD structure in different ethnic populations [81].

Meta-analysis of gene set analysis (META-GSA)

Investigating the genetic basis of complex diseases and identifying their molecular mechanism using GWAS results has become a research target for personalized medicine. As a result, gene set analysis procedures were suggested as complementary approaches to ascertain the genetic basis of a disease, by searching for sets of genes sufficiently enriched with significance for an association with phenotype [68,71,82,83]. Most gene set analysis approaches generate no effect estimates, rather *P*-values obtained from one-sided statistical tests. Those *P*-values are computed based on SNPs GWAS summary information belonging to specific genes involved in a pathway using a gene-pathway annotation database [83]. However, minor alleles from these markers can be observed simultaneously as risk factors in one study and as protective factors in another. Thus, the significance of a gene set may occur simultaneously with a lack of concordance patterns observed among SNPs associated with phenotype [84]. It is motivated by this observation that Rosenberg and colleagues [84] developed an approach (META-GSA) which aimed at aggregating *P*-values of gene set analyses accounting for the concordance of the signs of single-marker-association point estimates and related *P*-values of all SNPs assigned to genes contained in the gene set. The hub aspect of this approach is the introduction of directed *P*-value and the pooling of gene set *P*-values. The performance of META-GSA follows four necessary steps which use marker-specific information and study-specific weight to ascertain the null distribution of the test statistics as well as its overall significance.

META-GSA has been found to be applicable to any gene set analysis method, with the possibility of adding individual participants' genotype data, which seems more powerful than methods based on GWAS summary statistics. However, the model is limited by its reliance on SNP, gene and pathway annotations in databases, which are currently incomplete. Furthermore, the model generates *P*-values and does not provide effect estimation, hence reflecting incomplete activity information at the pathway/gene set level.

Other methods

Besides the method described in our previous sections, additional methods have been proposed to conduct MAPE. For instance, Kaever and colleagues [85] introduced a framework which performs meta-analysis of *P*-values secured from pathway enrichment analysis of multiple dependent or independent data sets from different omics platforms. For independent *P*-values, the framework either makes use of Fisher's [86] to combine *P*-values into a chi-square distribution, or Stouffer's [87] method to combine *P*-values into a normally distributed random variable. For dependent *P*-values, the model applies Brown's method [88] from a scaled chi-squared distribution, and a covariance matrix between data sets estimated from the standard normal deviates of the pathway-specific *P*-values, which were obtained for each single data set in Pathway Enrichment Analysis [89]. The tool has the advantage to ascertain the correlation between different data sets and condense the outcomes of multiple analyses but also distinguishing experiment-specific key pathways [85]. Furthermore, Nguyen *et al.* [90] developed a bi-level meta-analysis framework in the context of pathway analysis. This method split each data set into small dataset in which pathway analysis is being performed, then combine each data sets for each pathway using either an additive method or central limit theorem to ensure the accuracy of the outcome indicators [90]. The output sorts a list of pathways ranked according to the combined *P*-values adjusted for multiple comparisons using False Discovery Rate.

Challenges in pathway-based meta-analysis

Pathway-based meta-analysis methods have paved the way to detect novel pathways/gene sets significantly enriched in a phenotype of interest. However, one of the challenges facing this approach is the availability of gold-standard datasets. Though many consortia are being set up to build a standardized database, many remain to be done in terms of harmonization, and this could facilitate the development of a better statistical approach and help evaluate the current methods. In addition, with the availability of the aforementioned methods, there has been no concrete evaluation between them to ascertain the sensitivity and specificity of their measures either at the meta-analysis stage or at the pathway stage. It is also noteworthy to mention that genes often have multiple functions and the presence of an associated gene in a pathway does not necessarily establish a pathway-level association despite the model being used [83]. Importantly, due to the presence of multifunctional genes (genes involved in several biological functions or molecular processes), gene set overlap may occur, and these aforementioned methods ignore this overlap which is an integral part of gene set databases. Gene set overlap is an important challenge that needs to be investigated to address the pleiotropic effect of gene sets [91]. Quantitative approaches for pathway-based meta-analysis make use of well-known gene set databases as input in the pathway analysis step. Hence, the choice of the gene-set database has a significant effect in the analysis workflow [68]. Moreover, genes associated with phenotypes are not well represented. Then, an evaluation of the appropriate gene-set database is needed to better conduct pathway-based analysis and meta-analysis [68,91].

In general, GWAS meta-analysis whether at SNPs, gene or pathway level carries some limitations that require an undertaking to help improve the accuracy of statistical outcomes and make relevant implications. The hypothesis that different datasets are sampled independently is an important assumption in GWAS meta-analysis. Individuals overlap across datasets may result in a similar association signal in each dataset, artificially confirming this signal and leading to a spurious association reported by the meta-analysis. Because individuals in a given dataset are exposed to a particular environmental influence that causes a gene–environment interaction, an association signal may be present in one dataset but not in another. Individuals in both datasets may be genetically vulnerable to this impact, but it will not be noticed in one dataset due to the absence of the environmental effect. This might result in erroneous negative findings in comparison analyses once more. A similar scenario can occur when a gene–gene interaction influences phenotype and the relevant interacting genotype is present in one dataset but not the other. The same gene may then be related to only one of the two datasets. Moreover, population structure can lead to the discovery of specific loci associated with phenotypes that are simply tied to geography and local environmental realities that affect the

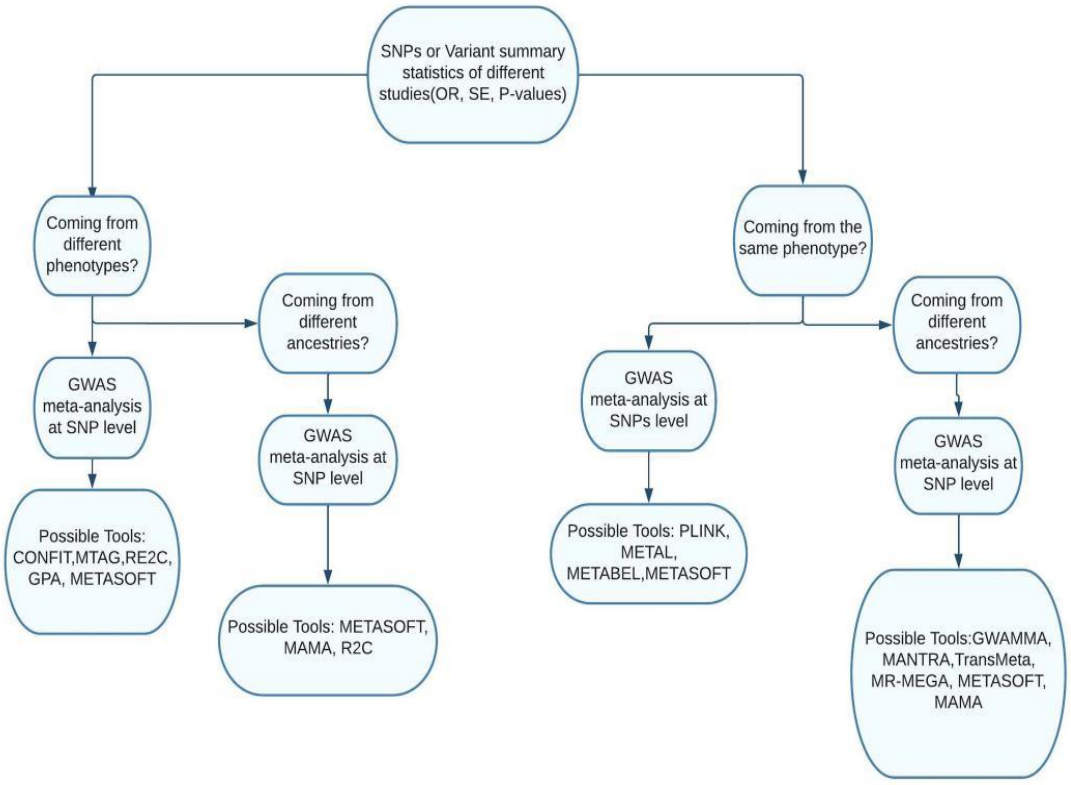

Figure 1. Similarities and differences with possible tools at SNP-level meta-analysis.

phenotype. Furthermore, as in genome-wide association research on a single dataset, these systematic ancestral discrepancies between distinct phenotypic classes can contribute to misleading relationships. Because of this possible confounder, if two or more traits are highly correlated with kinship, they may display shared genetic-association signals. When meta-analysing, FEM is usually carried out, in which the effect of a genetic variant is considered to be the same across all datasets. Although the FEM is the most popular approach to meta-analysis, if the datasets reveal significant genetic heterogeneity, the abovementioned assumption will be violated. As a result of the latter, it will yield inflated *P*-values, false-negative and false-positive findings. Because multiple genotyping technologies are used, distinct sets of genetic markers are frequently included in different datasets. As a result, the SNP having the strongest association in one dataset may be absent from another. This necessitates either: (i) limiting the analysis to SNPs present in all datasets issued from the same genotypic platform, (ii) assessing the score at the gene level rather than the SNP level or (iii) imputing missing SNPs in each dataset [92]. If the studies to be included in a comparative analysis or meta-analysis were imputed using different techniques and/or different haplotype panels obtained from a different ethnic population than the intended one, the data will be more heterogeneous.

To sum up, GWAS meta-analysis has become a valuable technique to increase the power of association of functional units whether variant, gene or set of genes involved in the same pathway. Though this technique mostly makes use of SNPs information, but its application can also be extended at structural variation summary information. Such an approach has helped validate numerous replicable genes increasing the risk of various

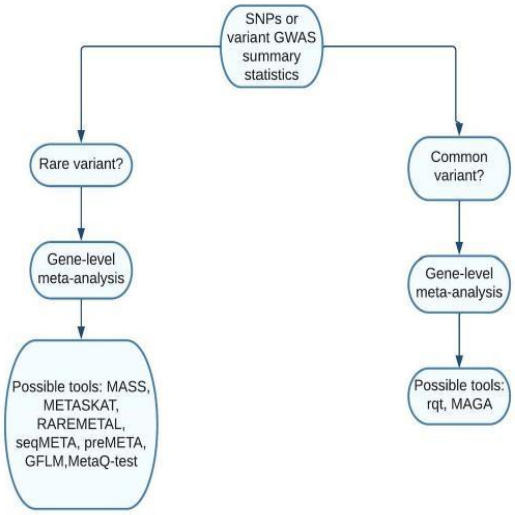

Figure 2. Similarities and differences with possible available tools at gene-level meta-analysis.

complex phenotypes or diseases and has suggested targets for biological follow-up and drug development. However, false-positive discoveries (type I or type II errors) can result from a variety of factors, including ascertainment bias, phenotyping or genotyping error, population structure or cryptic relatedness.

ancMETA	Bayesian graph-based framework to perform gene and sub-network/pathway specific meta-analysis accounting for the variation of effect sizes across multiple independent GWAS studies	SNP summary statistics + SNP-gene information + gene-gene information + gene-pathway information	sub-networks and enrichment of top significant central subnetwork	https://github.com/echimusa/ancMETA

These factors can also misdirect expensive downstream functional research. Hence, addressing these shortcomings may bring confidence in the design, replication and discoveries of new association signals. Finding a suitably powered reliable dataset becomes more difficult as GWAS discovery sample sizes increase since newly found loci tend to have smaller effect sizes or come from variations with uncommon MAF [93]. The replicability issue is not expressly addressed by most of the meta-analysis methods. When some of the contributing studies have spurious positive signals, these methodologies may result in biased meta-analysis conclusions. In actuality, some worthwhile procedures may be used to assess the validity of the findings in the case where the association signal is supported by a certain number of participating studies or if the genetic effect's heterogeneity between genetically similar populations is low, which can make the findings difficult to replicate and generalize. The significance of association after combining each cohort cannot always be considered a reliable indicator for replicability because large datasets give more significant *P*-values in comparison to smaller studies when the estimated association effect size (either real or spurious) is the same.

Besides, GWAS meta-analysis, there is a need to develop in-principle methods for assessing the replicability of findings. One can attempt to compare meta-analysis outcomes with and without removing low-frequency variants from imputation-based GWAS. The other option is to develop an appropriate indicator to measure the strength and the consistency of the signals between biological replicates accounting for the difference in sample sizes between cohorts.

In addition, not all methods can be utilized for GWAS meta-analysis studies, depending on the data on hand and the expected outcome. For instance, if GWAS studies come from the same phenotype, METAL or METASOFT can be employed; however, if the GWAS studies come from different phenotypes with statistical information on overlapping SNPs, then METAL of METASOFT might not be appropriate. Similar thing applies in the case where the GWAS studies originated from different ancestries with the same phenotype of different phenotype. In the same way, what may be working for common variant might not be working for rare variant. The difference and relatedness of each method and the possible tool which can be applied based on the data on hand are suggested in Figures 1 and 2. The user needs to appropriately choose the tool which perform GWAS meta-analysis whether at SNP, gene or pathway level depending on the available information on hand. The avenue is then opened to develop methods which account for all these varieties whether at SNPs, gene or pathway level to retrieve important information with relevant implications.

Conclusion

In this paper, we reviewed a set of popular methods for meta-analysis at SNP, gene and pathway levels. We highlighted the statistical models underlying the frameworks and discussed some of their strengths and shortcomings. We also pointed out some avenues of investigation, especially at the pathway level. Though association signal is driven by the association of variant (or set of variants), the prediction of these variants to the underlying phenotype has grown to become a relevant avenue to understand their roles on traits across population. This approach utilizes polygenic risk score to ascertain the prediction of a variant to the phenotype. Even though it is not the focus of our review, one avenue would be to survey different methods of polygenic risk score at different level highlighting their similarities and differences. Currently, pathway-based meta-analysis plays an important role and represents the best way to unveil sets of genes involved in disease aetiology and disease mechanisms. The workflow of this approach varies from situation to situation and method to method depending on the input data, the statistics used to assay the meta-analysis at gene level, the pathway database used to annotate the gene sets and the measures for association at the pathway level (Table 4). Each of these methods has its potential and limitations. Leveraging the potential of these methods offers an opportunity for novel discoveries, whereas existing limitations

Downloaded from https://academic.oup.com/bib/article/24/1/bbac600/6972298 by University of Cape Town Libraries user on 02 October 2023

mean much research work remains to provide robust frameworks for association tests. As GWAS continue to grow in sample size, developing pathway-based meta-analysis approaches using GWAS summary statistics provides a greater opportunity to identify novel pathway association. However, sARTP, ancMETA and META-GSA approaches are presently the sole methods which integrate summary statistics-level input data in the analysis process. The door is wide open to developing new methodologies including statistical approaches with appropriate datasets to improve and ascertain our findings and address new research questions that could arise.

Key Points

- Introduction of the three categories of Genome-Wide Association Studies meta-analysis found amidst in the literature which includes the SNP-based, gene-based and pathway-based GWAS meta-analysis and the method being employed.
- Summary description and outline framework of these methodologies at each level.
- Discussion of the strengths and pitfalls of GWAS meta-analysis approaches within various categories.

Supplementary Data

Supplementary data are available online at https://academic.oup.com/bib.

Data availability

No datasets were generated or analyzed during the current study.

Acknowledgements

We would like to thank Dr Armin Deffur for helpful discussions, support and guidance in the preparation of the manuscript.

Dissecting Meta-Analysis in GWAS Era: Bayesian Framework for Gene/Subnetwork-Specific Meta-Analysis

Emile R. Chimusa and Joel Defo*

Division of Human Genetics, Department of Pathology, Institute of Infectious Disease and Molecular Medicine, University of Cape Town, Cape Town, South Africa

Over the past decades, advanced high-throughput technologies have continuously contributed to genome-wide association studies (GWASs). GWAS meta-analysis has been increasingly adopted, has cross-ancestry replicability, and has power to illuminate the genetic architecture of complex traits, informing about the reliability of estimation effects and their variability across human ancestries. However, detecting genetic variants that have low disease risk still poses a challenge. Designing a meta-analysis approach that combines the effect of various SNPs within genes or genes within pathways from multiple independent population GWASs may be helpful in identifying associations with small effect sizes and increasing the association power. Here, we proposed ancMETA, a Bayesian graph-based framework, to perform the gene/pathway-specific meta-analysis by combining the effect size of multiple SNPs within genes, and genes within subnetwork/pathways across multiple independent population GWASs to deconvolute the interactions between genes underlying the pathogenesis of complex diseases across human populations. We assessed the proposed framework on simulated datasets, and the results show that the proposed model holds promise for increasing statistical power for meta-analysis of genetic variants underlying the pathogenesis of complex diseases. To illustrate the proposed meta-analysis framework, we leverage seven different European bipolar disorder (BD) cohorts, and we identify variants in the angiotensinogen (*AGT*) gene to be significantly associated with BD across all 7 studies. We detect a commonly significant BD-specific subnetwork with the *ESR1* gene as the main hub of a subnetwork, associated with neurotrophin signaling ($p = 4e^{-14}$) and myometrial relaxation and contraction ($p = 3e^{-08}$) pathways. ancMETA provides a new contribution to post-GWAS methodologies and holds promise for comprehensively examining interactions between genes underlying the pathogenesis of genetic diseases and also underlying ethnic differences.

1 INTRODUCTION

The main goals of trait mapping studies, including genome-wide association studies (GWASs), are to understand the genetic architecture of diseases, pinpoint the number of loci associated with a particular trait, and approximate the underlying heritability rate (Hirschhorn and Daly, 2003; Cantor et al., 2010; Wray et al., 2010; Garfield, 2020). Once the disease-causing variants and genes are

identified, this information will help researchers who are working in clinical, medical, or public health fields to establish prevention strategies, predict risks, and adapt therapeutic measurements Hirschhorn and Daly (2003); Cantor et al. (2010); Tam et al. (2019); Nguyen and Eisman (2020); Legge et al. (2021). Regardless of the successes, GWASs are still confronting many challenges and limitations Hao et al., 2019); Zhu et al. (2017) and have received considerable criticism (Zuka et al., 2012; Cantor et al., 2010). The challenges faced by GWASs include 1) the translation of the associated loci into suitable biological hypotheses (Zuka et al., 2012); 2) the issue of missing or hidden heritability (Kang et al., 2010; Hirschhorn and Daly 2003), which has now been partially tackled; 3) the understanding of how multiple modestly associated variants within genes interact to influence a phenotype (Wang et al., 2007; Hao et al., 2019; Tam et al., 2019); 4) the imperfection of asymptotic distribution of the current mixed model association or logistic regression in the specific case of low-frequency variants (Chimusa et al., 2012; Hao et al., 2019); and 5) the inefficiency in distinguishing between inflation from bias (from cryptic relatedness and population stratification) to the true signal from polygenicity (Chimusa et al., 2012; Hao et al., 2019; Tam et al., 2019).

These limitations reflect a gap in our understanding of the mechanisms underlying the pathogenesis of complex traits and diseases. The major source of these shortcomings is the method of GWAS itself as restricted to a single-marker-based testing approach (Wang et al., 2007; Hao et al., 2019; Tam et al., 2019). Various post-GWAS approaches have been proposed to address the single-SNP-based GWAS limitation (Jia et al., 2011; Wu et al., 2009; Wang et al., 2010; Peng et al., 2008), which are different in many aspects, but all are driven by the need to extract useful information from the GWAS summary statistics. The GWAS meta-analysis has become an increasingly adopted method that leverages association summary statistics to fostering a culture of compulsory *in silico* replication to maintain reliability in genetics association findings Ilya et al. (2017); Duarte et al. (2019); Shen and Tseng (2010); Lu et al. (2018). A meta-analysis framework combines results from different GWAS cohorts and puts them in one analysis framework to recover signals that one single GWAS cohort study mighty be missed and address the between-study and between-population heterogeneity Kavvoura and Ioannidis (2008); Thompson et al. (2011). In the last decade, the use of meta-analysis method has increased due to different interests from both the medical researchers and statisticians Shi and Lee (2016); Fan et al. (2016); Turley et al. (2018). Recently, meta-analysis has shown remarkable discovery results and helped to more understand and validate association results from different studies. The meta-analysis is considered as post-genome-wide association study method Chimusa et al. (2012); Han and Eskin (2011); Lu et al. (2018); Shi and Lee (2016). Despite the instrumental findings from single-SNP-based meta-analysis, there remains a need for a single comprehensive analysis that can both aggregate from the diverse population GWAS and incorporate the effect of multiple markers and other potential factors at a gene or pathway level. Heterogeneity among the GWAS meta-analyses remains an issue, particularly when the number of studies increases Han and Eskin (2011); Kavvoura and Ioannidis (2008); Thompson et al. (2011). This raised challenge on the power of GWAS meta-analysis across diverse population cohorts of differing genetics ancestry. Moreover, critical caution is required since incomplete replication can also be informative as several studies reported lack of interpopulation replicability, indicating that some risk variants are population-specific Hirschhorn and Daly (2005); McCarthy et al. (2008); Newton-Cheh and Hirschhorn (2005). For example, comparing the Asian and European associations with major depression, the failure of replication is largely due to the difference in the partner of linkage disequilibrium (LD), which reduces power in one population since the proportion of attributable risk declines with a population-specific minor allele frequency Newton-Cheh and Hirschhorn (2005). A caveat, however, is that fewer GWASs conducted in the non-European ancestry usually constitute of fewer samples Newton-Cheh and Hirschhorn (2005), raising the question as to how the clinical utility of GWASs can be made equitable across multi-ethnic populations Martin et al. (2021); Torkamani et al. (2018) and, specifically, how to accurately predict health and disease risks in the African populations. Furthermore, variation of the cohort size across independent studies is challenging, especially when these studies have been conducted from distinct populations of different ancestries and patterns of LD Chimusa et al. (2012); Han and Eskin (2011); Kavvoura and Ioannidis (2008); Thompson et al. (2011).

While the factors may raise heterogeneity Chimusa et al. (2012); Han and Eskin (2011); Kavvoura and Ioannidis (2008); Thompson et al. (2011), designing a gene-based and subnetwork/pathway-based meta-analysis may be helpful in pooling information from multiple population GWASs and multiple variants within a gene or genes within pathways or subnetworks Shi and Lee (2016); Fan et al. (2016); Turley et al. (2018); Ilya et al. (2017); Duarte et al. (2019); Shen and Tseng (2010); Lu et al. (2018). This may reveal larger effects and provide valuable information to prioritize the most important results across human populations. We refer to this approach as gene- or subnetwork/pathway-specific meta-analysis. Similarly, the list of new post-GWAS tools, such as multi-marker analyses, which go beyond single SNP tests, or the inclusion of functional evidence to reweight GWAS results, is growing by the day Newton-Cheh and Hirschhorn (2005); Chimusa et al. (2012); Shi and Lee (2016); Fan et al. (2016); Turley et al. (2018); Ilya et al. (2017); Duarte et al. (2019); Shen and Tseng (2010); Lu et al. (2018). Although many methods for meta-analysis have been developed over the past decades, the methodology still faces significant limitations. In particular, the challenge of low statistical power is still unresolved, as demonstrated by the fact that meta-analyses have not necessarily resulted in an increased statistical power Li et al. (2012). This is, in part, due to the analysis methods failing to optimally account for the high degree of between-study

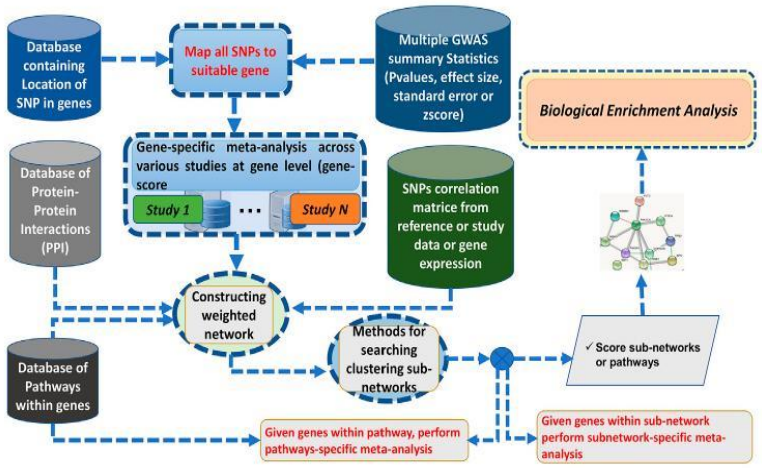

FIGURE 1 | Flowchart of ancMETA.

heterogeneity that characterizes most meta-analyses of the datasets Shi and Lee (2016); Fan et al. (2016); Turley et al. (2018); Duarte et al. (2019); Lu et al. (2018). Apart from power considerations, another important challenge is the translation of statistical association in meta-analyses into biologically meaningful insights.

Here, we addressed some GWAS meta-analysis limitations by proposing a Bayesian graph-based framework to perform the gene/pathway-specific meta-analysis by combining the effect size of multiple SNPs within genes, and genes within subnetwork/pathways across multiple independent population GWAS to deconvolute the interactions between genes underlying the pathogenesis of complex diseases across diverse populations (**Figure 1**).

We assessed the proposed framework on simulated datasets, and the results show that the proposed model holds promise for increasing statistical power for meta-analysis of genetic variants underlying the pathogenesis of complex diseases. We illustrated it in 7 different European bipolar disorder (BD) cohorts, and we finally outlined the implications, challenges, and opportunities that cross-ancestry meta-analyses present in the GWAS era. The proposed method has been implemented in the ancMETA tool https://github.com/echimusa/ancMETA, providing a new contribution to post-GWAS methodologies, and holds promise for deconvoluting interactions between genes underlying the pathogenesis of genetic diseases and underlying ethnic differences.

2 MATERIALS AND METHODS

2.1 Details of Gene/Subnetwork-Specific Meta-Analysis

Here, we discuss the proposed meta-analysis framework, ancMETA. It performs meta-analysis at two different levels by aggregating multiple independent population GWAS summary statistics datasets. It uses an integrative analysis through Bayesian posterior probability and combines the results into known biological protein–protein network datasets. Lastly, ancMETA performs the meta-analysis at the subnetwork level and identifies the most significant subnetworks to understand the biological pathways (**Figure 1**).

We describe six different steps of the proposed meta-analysis framework as follows:

Step 1: Collection of N-independent studies.

This step requires $N \geq 2$ independent GWAS summary statistics datasets, from the same phenotype or trait. GWAS summary statistics are defined here as per-genetic locus effect sizes (log odds ratios) together with their standard errors, p-values, or z-scores for the affected–unaffected traits de Leeuw et al. (2015); Il-Youp and Wei (2015); Huang et al., 2016); Wang et al. (2017).

Step 2: Mapping SNPs to the associated genes.

This is an intermediate step, and it is similar to our previous approach Chimusa et al. (2015), where all the SNPs are mapped to their related genes. It is common practice to assign SNPs to the genes based on a distance cutoff, and the previous studies use a variety of cutoffs, such as distance from 2 to 500 Kbps Conti et al. (2009); Brodie et al. (2016); Chimusa et al. (2015); Wang et al. (2010, 2007). ancMETA allows users to specify the distance cutoffs of assigning SNPs down-/upstream to a specific gene (see the **Supplementary Material**). At this step, the combined statistical outcomes (i.e., the effect size and the standard error) are computed, as illustrated in **Figure 1**.

We assume that the *ith* study (i = 1, 2,. . ., N) has J_i genes G_j^i ($j = 1, 2, \ldots, J_i$), each having a set of specific SNPs, where N is the total number of studies. Let $S = \cup_{i,j} S_j^i$ denote the set of all SNPs, where S_j^i is the set of SNPs at the *jth* gene of the study i. For an SNP $s \in S_j^i$, let $\beta_j^i(s)$, $\zeta_j^i(s)$, and $p_j^i(s)$ represent the effect size,

the standard error, and the p-value, respectively. The proposed meta-analysis framework assumes that the SNPs related to one gene are correlated. This assumption is due to the fact that each gene contains a large number of SNPs mostly under LD; therefore, the magnitude of the statistical outcomes for each SNP within a gene from each study is considered to be approximately the same. Thus, the effect size and the p-value will follow a normal distribution. Let μ_j^i be the unknown true effect size at the jth gene G_j^i of study i ($i = 1, 2,\ldots, N$; $j = 1, 2,\ldots, J_i$). Thus, a fixed-effects model can be applied to estimate the combined effect size at the gene level from each study $i = 1, 2, \ldots N$. We construct a linear function of parameters μ_j^i as follows:

$$x = y(\beta, \mu) = \sum_{s \in S_j^i} \beta_j^i(s)\mu_j^i.$$

Let $V_j^i(s)$ be the variance. Then, the estimation of the combined effect size is given as follows:

$$\begin{aligned} p\left(x|B_j^i, \mu_j^i, V_j^i\right) &= \mathcal{N}\left(x|B_j^i\mu_j^{iT}, V_j^i\right) \\ &\sim \prod_{s \in S_j^i} \frac{1}{\sqrt{2V_j^i(s)\pi}} \exp\left[-\frac{\left(\beta_j^i(s) - \mu_j^i\right)^2}{2V_j^i(s)}\right]. \end{aligned} \quad (1)$$

Note **Eq. 1** is the likelihood when $\mu \neq 0$. Although the solution, which corresponds to the maximum true effect size μ_j^i at gene G_j^i, can be approximated from sampling approaches, **Eq. 1** can be solved analytically by differentiating the log likelihood and setting it to 0, that is,

$$\frac{\partial \log\left(p\left(x|B_j^i, \mu_j^i, V_j^i\right)\right)}{\partial \mu_j^i} = 0$$

or

$$\sum_{s \in S_j^i} \left[\frac{\beta_j^i(s) - \mu_j^i}{V_j^i(s)}\right] = 0. \quad (2)$$

Eq. 2 can be written as

$$\sum_{s \in S_j^i} \left(V_j^i(s)\right)^{-1} \beta_j^i(s) - \sum_{s \in S_j^i} \left(V_j^i(s)\right)^{-1} \mu_j^i = 0.$$

Hence, the estimated effect size of gene G_j^i is given as

$$\hat{\mu}_j^i = \frac{\sum_{s \in S_j^i} \left(V_j^i(s)\right)^{-1} \beta_j^i(s)}{\sum_{s \in S_j^i} \left(V_j^i(s)\right)^{-1}}.$$

Therefore, its standard error is derived as

$$sd\left(\hat{\mu}_j^i\right) = \left(\sqrt{\sum_{s \in S_j^i} V_j^i(s)}\right)^{-1}.$$

Step 3: Meta-analysis at the gene level.

Let β_j^i and ζ_j^i be the combined statistical outcomes (i.e., effect size and standard error, respectively). Since the effect size may be different across the studies, the heterogeneity between the studies may be high. A parameter σ_j^2, which accounts for between-study variability, is introduced. Because the maximum-likelihood method underestimates the variance when the number of studies is small DerSimonian and Laird (1986), we use the unbiased method of moments Borenstein et al. (2010) to compute the variance components as follows:

$$\sigma_j^2 = \frac{1}{N}\sum_{i=1}^{N}\left[\beta_j^i - H_j\right]^2,$$

where $H_j = \frac{1}{N}\sum_{i=1}^{N}\beta_j^i$. It is assumed that the true effect size of the gene G_j is $\mu_j + \sigma_j^2$, where μ_j is an unknown parameter. The same calculations as in step 2 are applied to estimate the effect size of the gene G_j across the studies, which is calculated as follows:

$$\hat{\mu}_j = \frac{\sum_{i=1}^{N}\left(\sigma_j^2 + V_j^i\right)^{-1}\beta_j^i}{\sum_{i=1}^{N}\left(\sigma_j^2 + V_j^i\right)^{-1}},$$

and its standard error is given as follows:

$$sd\left(\hat{\mu}_j\right) = \left(\sqrt{\sum_{i=1}^{N}\left[\sigma_j^2 + V_j^i\right]}\right)^{-1}.$$

If the precision ρ^i of the study ith for $i = 1, 2,\ldots, N$ is equal to $\frac{1}{(\mu^i)^2}$, then the heterogeneity statistic, using Cochrane's test (Q) is given as follows:

$$Q = 100 \times \sum_{i}^{N} \rho^i\left(\hat{\mu}_j - \theta\right)^2, \quad (3)$$

where $\theta = \frac{\Sigma_i^N \rho^i \hat{\mu}_i}{\Sigma_i^N \rho^i}$ is a weighted estimator, and $Q \sim \chi_{N-1}^2$ under the null hypothesis that the between-study variance $\tau^2 = 0$. If we consider the expectation of **Eq. 3**, the between-study variance is given as

$$\tau^2 = \frac{Q - (N-1)}{\Sigma_i^N \rho_i - \left(\frac{\Sigma_i^N \rho_i^2}{\Sigma_i^N \rho_i}\right)}.$$

Since the test statistics in **Eq. 3** has N − 1 degree of freedom (df), then for $Q < df$ (which means $\tau^2 < 0$), the maximum between 0 and τ^2 is considered, so that τ^2 is non-negative. Recalling that in

Algorithm 1 : The procedure to generate a sub-network is similar to our recent method.

(1) **Input**: A mapped network G, which contains the genes that are weighted by effect sizes, standard error and LD.
(2) From the network G, find structural hubs and connected components.
(3) For each gene, compute the betweenness, the closeness and the eigenvector scores.
(4) For each centrality score, compute the cut-off for central genes of sub-graphs.
(5) Consider a gene as a hub if its score is greater than or equal to the corresponding cut-off.
(6) Consider a gene as a central gene if it is hub for all the four scoring measures in step (3).
(7) For each central gene, search its neighbours for n iteration, or the mean shortest path. The central gene and its neighbours constitute a sub-network of the network G.
(8) **Output**: sub-networks and enrichment of top significant central sub-network.

step 2, we pointed out that SNPs within one gene are correlated. Therefore, to perform meta-analysis, a fixed-effects model is used Borenstein et al. (2010).

Step 4: Mapping genes to biological networks.

For this step, all the genes and their related statistical outcomes and gene–gene combined LD are mapped into a PPI network database (**Supplementary Material**), which contains information on interactions among the genes. Therefore, the genes are considered as weighted nodes with their related statistical outcomes (i.e., effect size and standard error), and the edges represent the interactions between the genes (nodes), which are weighted with the combined LD, for each pair-wise genes (nodes) that have a link. More details can be found in **Supplementary Materials**. The details of the combined LD can be found in **Supplementary Text S1**.

Step 5: Meta-analysis at the subnetwork level. This step estimates the effect size and standard error of each subnetwork from . **Supplementary Text S1** provides more details of different concepts used in . The procedure is the same as that of step 3, where it is assumed that there is a heterogeneity between the genes in each subnetwork. Let ρ_j^2 be the between-gene heterogeneity, β_j^i be the observed effect size, and ζ_j^i be its standard error. If μ is the unknown true effect size at the subnetwork level with K genes, the estimated effect size is given by $p(x|\beta_j^i, \mu_j^i, V_j^i + \rho_j^2) \sim$

$$\prod_{G_j^i \in K} \frac{1}{\sqrt{2\left(V_j^i + \rho_j^2\right)\pi}} e^{\left[-\frac{\left(\beta_j^i - \mu_j^i\right)^2}{2\left(V_j^i + \rho_j^2\right)}\right]}. \tag{4}$$

Since **Eq. 4** is considered to be the likelihood when $\mu \neq 0$, maximizing the log likelihood by solving

$$\frac{\partial \log\left(p\left(t|\beta_j^i, \mu, V_j^i + \rho_j^2\right)\right)}{\partial \mu_j^i} = 0$$

yields

$$\hat{\mu}_j^i = \frac{\sum_{G_j^i \in K}\left(\rho_j^2 + V_j^i\right)^{-1}\beta_j}{\sum_{G_j^i \in K}\left(\rho_j^2 + V_j^i\right)^{-1}}, \tag{5}$$

Algorithm 2 : The specification of proposed meta-analysis Framework.

(1) GWAS summary statistics (Effect sizes, the standard errors, p-value and LD), for each study i = 1,…, N

(2) For each study i = 1, …, N map SNP in GWAS summary statistics to gene if the SNP is located within that gene's primary transcript or 40 kilobases (kb) downstream or upstream.

(3) Assuming SNPs within a gene are dependent (or correlated), from study i ($i = 1, \ldots, N$) compute the overall p-value, the effect size and its standard error for gene G_j^i ($j = 1, \ldots, M$) following a fixed model.

(4) Given the estimated effect size and its standard error (at gene level) in the study i ($i = 1, \ldots, N$), compute the posterior probability e^i that the effect exists, the between-study variance and the heterogeneity at gene G_j^i. Construct the weighted sum of the $z - score$ from the Binary effect (or random effect) model and estimate the p-value from $z - score$ value.

(5) Map the set G = $\{G_1, \ldots, G_M\}$ of genes to PPI network and weight each edge by computing the LD between genes using the genotype data of the population under study.

(6) Map the set G = $\{G_1, \ldots, G_M\}$ of genes to the weighted Gene Ontology (GO) network.

(7) Transform network in steps (5) and (6) to an integrated weighted network whose nodes are weighted by p-values, the effect sizes and their standard errors from studies ($i = 1, \ldots, N$). The new edges are weighted by a transformed weight from both networks in steps (5) and (6).

(8) Break down the resulting network in (7) into sub-networks using the algorithm 1.

(9) Assuming, that genes within a given sub-network are independent, for each study i ($i = 1, \ldots, N$), compute the overall p-value, effect size and its standard error for each sub-network following a standard random model.

(10) Repeat step 4 for sub-networks level.

(11) Output file contains cross populations meta-analysis summary signals each sub-network, biological pathway enrichment of the top significant sub-network and its meta-analysis forest plot.

and its standard error estimated effect size is given as

$$sd\left(\hat{\mu}_j^i\right) = \left(\sqrt{\sum_{G_j^i \in K}\left[\rho_j^2 + V_j^i\right]}\right)^{-1}.$$

Step 6: Computing the overall statistical significance.

From step 5, we know that β_j^i and ζ_j^i represent the observed effect size and the standard error, respectively, where $\hat{\mu}_j^i$ as the unknown effect was estimated using **Equation 5**. For this step, let us consider the Bayes' theorem, which includes all the possible effect outcomes for N studies, and let us apply the symmetrical property of the Gaussian distribution. Therefore, the posterior probability is approximately given as

$$\begin{aligned} \hat{e}_j^i &= \frac{\pi \int_{\mathbb{R}} \mathcal{N}\left(\beta_j^i|\hat{\mu}_j^i, \zeta_j^i\right) p\left(\hat{\mu}_j^i\right) d\hat{\mu}_j^i}{(1-\pi)\mathcal{N}\left(\beta_j^i|0, \zeta_j^i\right) + \pi \int_{\mathbb{R}} \mathcal{N}\left(\beta_j^i|\hat{\mu}_j^i, \zeta_j^i\right) p\left(\hat{\mu}_j^i\right) d\hat{\mu}_j^i} \\ &= \frac{\pi \mathcal{N}\left(\beta_j^i|\hat{X}_j^i, \zeta_j^i + \hat{V}_j^i\right)}{(1-\pi)\mathcal{N}\left(\mu_j^i|0, \zeta_j^i\right) + \pi \mathcal{N}\left(\mu_j^i|\hat{X}_j^i, \zeta_j^i + \hat{V}_j^i\right)}. \end{aligned} \tag{6}$$

However, a test statistic based on the weighted sum of chi-square can be used, under the null hypothesis that there is no association. Thus, from the fact that e_j^i contains the information from all studies, it can be used as a prior weight in the weighted sum of the chi-square statistics as follows:

$$\hat{\chi}_j = \frac{\sum_{i=1}^N \hat{e}_j^i}{\sqrt{\hat{e}_j^i}} \frac{\left(\hat{\mu}_j\right)^2}{\left(\sum_{i=1}^N \zeta_j^i + \tau^2\right)}, \quad \tau^2 \geq 0,$$

where τ^2 is the between-study variance. Recalling that **Equation 6** is not normally distributed, the p-values can be evaluated through a sampling method developed by Han and Eskin (2011). puts together all the steps of the proposed framework.

2.2 Evaluation of ancMETA From Simulation GWAS Data

The U.S. residents of northern and western European ancestry (CEU), Yoruba (YRI), and Mexican (MEX) populations from the HapMap3 Project were used to generate independent case–control studies. Details of these populations can be found in **Supplementary Table S1**. We independently performed a population growth model on each dataset mentioned previously (**Supplementary Text S2**). From the resulting expanded datasets, we generated three independent case–control datasets based on chromosomes 1 and 22 using HapGen2 Su et al. (2011). Here, we randomly selected 3 SNPs on chromosome 1 and 3 other SNPs on chromosome 22 to be simulated as causal disease SNPs with differing effect sizes under HapGen2 Su et al. (2011). The simulated disease effect size parameters of those SNPs are summarized in **Supplementary Table S2**. These parameters are chosen to fit small effect size in some studies and strong in others. We simulated 1,000, 3,000, and 950 cases and 1,000, 3,000, and 1,000 controls from the haplotype

(combination of multiple SNPs) data of CEU, YRI, and MEX, respectively. We considered the simulated MEX GWAS dataset as our primary study. The simulation details can be found in **Supplementary Text S2**.

We conducted a GWAS on each dataset using EMMAX Kang et al. (2010). As expected and according to our simulation parameters (**Supplementary Table S2**), the GWAS results indicate significant, moderate, and weak signals of association in CEU, YRI, and MEX, respectively, as per simulation (**Supplementary Table S3** and **Supplementary Figure S1**). We used the resulting GWAS summary statistics as input in our proposed model, implemented in "ancMETA," to perform the gene- and subnetwork-specific meta-analysis (**Supplementary Text S3**).

At the gene level, the results in **Table 1** and **Supplementary Figure S2** show significant genes, including *CBX7*, *LD0C1L*, and *ASTN1* associated with our simulated causal SNPs (**Supplementary Table S2**). This result indicates further increase in the effect size across these 3 simulated case–control studies, compared to single-SNP tests in GWAS based on EMMAX (**Supplementary Table S3**). Interestingly, at a subnetwork level, we observed a significant convergence of effect sizes of the simulated disease variants across all the studies (**Figures 2A,B**), particularly to *CBX7* (**Table 1**). This supports the fact that the true effect risk-associated variants may differ across populations at the polymorphism level, but the effect may tend to convert at a similar magnitude at gene and pathway levels or overlap in the same biological subnetworks/pathways when aggregating several small polymorphism effects.

2.3 Application to Seven European With Bipolar Disorder Cohorts

Here, we used seven European bipolar disorder (BD) GWAS summary statistics obtained from the NIMH data repository (**Supplementary Table S1**). These datasets include Irish (IRI), Scottish (SCT), 3 European American (EUA), Norwegian (NOR), and British (BRB) individuals. **Supplementary Table S4** provides GWAS summary results of each of these studies. Leveraging the European reference panel from 1000 Genomes Project data, we first conducted the imputation LD fine-mapping from the obtained GWAS summary statistics using ImpG-Summary Pasaniuc et al. (1977) to possibly unravel more LD-SNP association (**Supplementary Figure S3**). The resulting imputation GWAS LD fine-mapping summary statistics were used as input for ancMETA. We performed the meta-analysis at a gene level across these 7 studies, and seven genes were identified (*AGT CACNA1C*, *ESR1*, *NCAN*, *BDNF*, *BCR*, and *GSK3B*), of which *AGT* has a strong effect across the European populations including Irish, Scottish, Norwegian, and British in contrast to the European American (**Supplementary Figures S4,5** and **Supplementary Table S5**).

Leveraging the recent version of the human PPI network (IntAct release 239) from the IntAct database Kerrien et al. (2012); Orchard et al. (2014), we observed a significant connected subnetwork where the estrogen receptor 1 (*ESR*1) gene is the main hub. *ESR1* interacts with *AGT* and is connected with the other gene hubs with known BD-associated genes such as *CACNA1C*, *PLCG2*, *NCAN*, *BCR*, and *BDNF*. **Supplementary Table S5** summarizes the association of the top subnetwork across these 7 studies. The identified subnetwork (**Figures 3A,B**) is significantly associated with the neurotrophin signaling ($p = 4e^{-14}$) and other interesting biological pathways such as myometrial relaxation and contraction ($p = 3e^{-08}$), morphine addiction ($p = 9.2e^{-08}$), DNA damage response ($p = 3e^{-05}$), and alcoholism ($p = 2e^{-05}$). In addition, the subnetwork (**Figure 3C**) is implicated in a positive regulation of transcription from RNA polymerase II promoter involved in neuronal differentiation ($p = 7.7e^{-21}$) and is also associated with autosomal dominant ($p = 2.8e^{-07}$) inheritance types of diseases (**Figure 3C**).

To evaluate the determined interconnectivity among *AGT*, *CACNA1C*, *ESR1*, *NCAN*, *BDNF*, *BCR*, and *GSK3B* as well as with the other protein-coding genes in **Figure 3**, and their association with BD, we leverage GeneMania Franz et al. (2018) to reconstruct the network shown in **Figure 3** based on physical and co-expressed interactions. The result from the reconstructed co-expression and physical interaction network of genes in **Figure 3A** confirms that the above 7 genes detected by ancMETA (**Figure 3A**) are physically and co-expressly interconnected **Figure 4** and as well as with other protein-coding genes in **Figure 3A**. From the enrichment analysis based on Enrichr Kuleshov et al. (2016), the network in **Figure 4** is significantly associated with neurotrophin signaling and other interesting biological pathways such as ErbB signaling pathways (**Figure 4**). Interestingly, recent studies have revealed that complex ErbB signaling networks regulate the assembly of neural circuitry, myelination, neurotransmission, and synaptic plasticity Mei and Nave (2014). Evidence indicates that there is an optimal level of ErbB signaling in the brain, and a deviation from it impairs brain functions. The ErbB signaling pathway may provide therapeutic targets for specific neuropsychiatric symptoms, and dysregulation in the ErbB signaling pathway may explain abnormalities of neural precursor migration in BD Mei and Nave (2014).

3 DISCUSSION AND CONCLUSION

Designing a post-GWAS meta-analysis that leverages the combined effect of multiple SNPs within a gene or genes within subnetworks/pathways across multiple GWAS datasets may reveal consensus association signals and identify large effect sizes. This may further provide valuable information in prioritizing the most important results across different populations. Here, we proposed a Bayesian graph-based gene- and pathway-specific meta-analysis approach. We implemented the proposed model in ancMETA (**Figure 1**), which addresses the variation in effect size across

TABLE 1 | Meta-analysis at gene and subnetwork levels from the simulated GWAS summary statistics across 3 studies: results show convergence of effects across studies to the simulated causal variants.

several independent GWAS summary statistics from distinct populations of different ancestry background. We assessed ancMETA through the simulation of different ancestries in three different GWAS studies.

A well-reconstructed human protein–protein interaction network is a powerful tool in network biology and medicine research, which forms the basis for multi-omics and dynamic analyses Mortezaei and Tavallaei (2020). However, the topology of the network and their connectivity may be very sensible from various pathway analysis methods Mazandu and Mulder (2011) in reflecting the relationship between certain biological processes or densely connected multi-protein complexes of biological relevance Franz et al. (2018); Kuleshov et al. (2016). This makes it challenging to compare the different post-GWAS pathway-based or network-based methods Jia et al. (2011); Chimusa et al. (2015); Wang et al. (2015); Mishra and Macgregor (2015); Huang et al., 2016; Wang et al. (2017); de Leeuw et al. (2015).

In addition to the GWAS summary statistics, ancMETA allows users to use any weighted biological network and accepts a user-defined network. In case if users provide an unweighted biological network, ancMETA leverages case–control genotype datasets to construct the weights of the network (**Supplementary Text S1**), in which the current post-GWAS approaches Fan et al. (2016); Turley et al. (2018); Ilya et al. (2017); Duarte et al. (2019); Shen and Tseng (2010); Lu et al. (2018); Mishra and Macgregor (2015); Huang et al., 2016; Wang et al. (2017); de Leeuw et al. (2015); Jia et al. (2011); Wang et al. (2015) do not account for. Evidence shows that many disorders are "polygenic" (many genetic loci contribute to risk) and reflect disruptions in proteins that participate and involve complex interactions between genes Dudbridge (2016); Khera et al. (2018). In contrast to other tools Shi and Lee (2016); Fan et al. (2016); Turley et al. (2018); Ilya et al. (2017); Duarte et al. (2019); Shen and Tseng (2010); Lu et al. (2018), ancMETA leverages the advantage of topological properties of biological networks to ascertain the interaction of proteins/genes that can be involved in a pathway. Our method accounts for the correlation that exists between the SNPs within a gene or genes within pathways and introduces flexibility in estimating the gene-specific and subnetwork-specific effect size, which, to our knowledge, is a new contribution to post-GWAS methodologies. The proposed framework holds promise for comprehensively examining the interactions between genes underlying the pathogenesis of genetic diseases.

Some improvements need to be considered in future work, such as accurately modeling the convergence of the SNP signal to the related subnetworks and leveraging the weakly/moderately associated signals from different GWAS studies. It is worth mentioning that we have applied ancMETA on old BD GWAS with a limited sample size (see **Supplementary Table S5**). However, regardless of the trait or phenotype used by the user in using ancMETA, the validity of the outcome will benefit and be improved by employing the powered GWAS summary statistics from GWAS datasets associated with larger numbers of samples (cases/controls).

There is also a need to integrate summary-level data across multiple phenotypes to simultaneously capture the evidence of the aggregate-level pleiotropic association. The lack of accurate knowledge of complex traits and the sensitivity of human protein interaction network makes it challenging to directly compare the results from the different pathway analysis methods. Overall, the method implemented in the proposed framework highlights the value of identifying the effect size of pathways associated with a disease, which may be useful in understanding the pathogenesis, disease risk prediction, and susceptibility to genetic diseases.

FIGURE 4 | Network reconstructed from genes in **Figure 3**, based on physical and co-expressed interactions obtained GeneMania Franz et al. (2018) and the top pathways of the reconstructed network from **Figure 3** obtained from various pathways databases in Enrichr Kuleshov et al. (2016).

The results obtained from the GWAS summary statistics on the European BD cohorts found association with seven genes, of which *CACNA1C* and *NCAN* have previously been implicated in BD through GWAS Bellantuono et al. (2007); Ferreira et al. (2008); Gordovez and McMahon (2020); O'Connell and Coombes (2021). This meta-analysis therefore strengthens these initial results and demonstrates that ancMETA can successfully validate GWAS findings. Interestingly, *AGT* has not reached GWAS significance in the previous studies despite being considered as a candidate in BD due to its role in the renin–angiotensin system Ferreira et al. (2008); Gordovez and McMahon (2020); O'Connell and Coombes (2021). The high significance for *AGT* from this analysis ($p = 3.2e^{-19}$) therefore strengthens its association with BD and further highlights the potential impact of ancMETA as a useful tool in discovering additional small effect variants that may be missed in the single GWAS. Importantly, the very interesting *AGT* finding is due to the innovations made in addressing population variation and to the inclusion of a PPI framework. The results from the subnetwork analysis revealed a strong interaction of the hub gene *ESR1* with *AGT*, as well as *CACNA1C*, *NCAN*, *BCR*, *GSK3B*, and *BDNF*, suggesting the fact that the *AGT* finding here is not merely indicative of a false positive, but rather that is valid. In addition to a moderate link to BD, *ESR1* has been related to migraine onset, alcohol dependence, obsessive compulsive disorder, and postpartum depression Alonso et al. (2011). The pleiotropy and genetic overlap between BD and these and other psychiatric phenotypes is a considerable complex Carmiol et al. (2014), suggesting that this analysis may have identified a key hub network and genetic underpinnings in not only BD etiology but also across several psychiatric phenotypes.

Supplementary Materials

1 SUPPLEMENTARY DATA

To evaluate our developed tool, we extracted three populations from HapMap 3 data sets http://www.sanger.ac.uk/resources/downloads/human/hapmap3.html. In each of the simulation we used whole-genome data of $1,604,948$ overlap SNPs, from the HapMap3 of 165 northern and western Europe (CEU), 203 Yoruba in Ibadan, Nigeria (YRI) and 86 Mexican ancestry in Los Angeles, California samples (see Table S1). To apply our developed tool, we used European population with Bipolar disorder (BD) GWAS datasets, with which we have been granted access, which are stored at the NIMH data repository. BD datasets comprised of seven different studies, with $3,793$ cases and $3,440$ controls in total (see Table S1).

2 SUPPLEMENTARY METHODS

We implemented the proposed model, called ancMETA using python programming language and made it available for public via this link (https://github.com/echimusa/ancMETA). Implemented module related functionalities to map the associated signal into protein-protein network and visualize the results of network statistics, are updated from our previous model Chimusa et al. (2015). The protein-protein interaction (PPI) dataset was manually updated from our previous method Chimusa et al. (2015), initially based on KEGG, BioCarta and Ambion GeneAssist Pathway Atlas pathway databases and from the recent version of the human protein-protein interaction (PPI) network (IntAct release 239) from IntAct database (Kerrien et al., 2012; Orchard et al., 2014). A topological test was performed on the constructed LD-weighted network of 21,429 pair-wise PPI network. The annotated human pathways was obtained from Zhang et al. (2012) and collected more from annotated pathways include the KEGG, BioCarta and Ambion GeneAssist Pathway Atlas pathway databases. We downloaded genomic coordinates for all genes from the NCBI ftp-server ftp://ftp.ncbi.nih.gov. All these data sets come along with ancMETA

2.1 Text S1:Leveraging the topological properties of network in searching clustered sub-networks

2.1.1 Searching for Sub-networks using Centrality Measures

Given two different sets of SNPs $S^a = \{s_i\}_{i=1,2,\ldots,m}$ and $S^b = \{s_j\}_{i=1,2,\ldots,n}$, $(s_i \neq s_j, i = 1, 2, \ldots, m$ and $j = 1, 2, \ldots, n)$ associated with genes G_a and G_b, the pair-wise LD between SNPs in S^a and S^b are computed using the r^2 measure Kristin et al. (2002) to get a combined LD. We provide two approaches for weighting (estimating the combined LD at the gene level) the interaction between genes in the Protein-Protein interaction network.

Case 1: Assuming sets of SNPs $S^a = \{s_i\}_{i=1,2,\ldots,m}$ and $S^b = \{s_j\}_{j=1,2,\ldots,n}$, $s_i \neq s_j$, for $i = 1, 2, \ldots, m$, and for $j = 1, 2, \ldots, n$ are assigned to genes G_a and G_b; and the pairwise LD of SNPs between G_a and G_b are independent. Because the distribution of the LD is not normal, thus from $(s_i \neq s_j)$ we compute the average z-transforms of LD from all possible combination of pairs of SNPs between genes G_a and G_b. The z-transforms of LD are normally distributed with mean 0 and variance 1 Choi (1977). We compute the combined LD between two genes G_a and G_b as follows,

$$r_{G_aG_b} = tanh\left(\frac{\sum_{i\neq j}^{N} tanh^{-1}\left(LD_{s_is_j}\right)}{N}\right). \tag{S1}$$

Case 2: Alternatively, if SNPs between a given pair of genes are dependent or correlated, we consider the maximum $r_{G_aG_b} = tanh(\max_{i \neq j}(tanh^{-1}\left(LD_{s_is_j}\right)))$ among all possible N pairs of SNPs between the given pair of genes.

The combined LD is used as the weight of the edge between G_a and G_b genes in the PPI network.

2.1.2 Searching for Sub-networks using Centrality Measures

Considering a weighted Protein-Protein interaction (PPI) network as an undirected network, $G = (V, E)$, where V is the set of n genes as nodes and E is the set of edges as interactions found between genes weighted using gene-correlation. To cluster G into sub-networks, we analyse the general properties of G and quantify the usefulness of each gene in G using their centrality scores; closeness, betweenness, degree or eigenvector. Let us first define the following centrality measures,

(1) **Degree Centrality:**
The degree centrality C_d of a gene in an undirected graph G is the number of genes in the network interacting with it.

(2) **Closeness Centrality Measure:**
The closeness centrality $C_{c(u)}$ of a node u in a network is the inverse of the average distance to all other nodes connected to it Mazandu and Mulder (2011), i.e., $C_{c(u)} = \frac{1}{\frac{1}{m}\sum_{v \in V_u} dist(u,v)}$, where V_u is the set of nodes connected to u, $m = |V_u|$ the number of nodes in V_u and $dist(u, v)$ is the shortest communication path between u and v in the network.

(3) **Communication Betweenness Centrality Measure:**
Let γ_{uv} be the number of communications between genes u and v, and $\gamma_{uv}(t)$ the number of shortest communications between u and v in the network G using t as an interior node, for $t, u, v \in V(G)$. The rate of communication between u and v, Δ_{uv} that can be controlled by an interior gene t, is given by

$$\Delta_{uv}(t) = \frac{\gamma_{uv}(t)}{\gamma_{uv}},$$

if $\gamma_{uv} = 0$, then we set $\Delta_{uv} = 0$. The shortest communication betweenness centrality $C_{spb}(t)$ is given by

$$C_{spb} = \sum_{u \in V \wedge u \neq t} \sum_{v \in V \wedge v \neq t} \Delta_{uv}(t).$$

(4) **Eigenvector Centrality Measure:**
The eigenvector centrality measure assigns relative weights to all genes in the network based on the fact that connections to high-weighted genes contribute more to the weight of the gene target. This means the weight or the contribution x_u of the gene u to the functioning of the system is proportional to the sum of the scores of all genes v connected to u, i.e.,

$$\sum_{(u,v) \in E} x_v = \lambda x_u$$

where λ is a constant of proportionality and x_z denotes the contribution of gene z.
In terms of the adjacency matrix $\mathcal{A} = (a_{uv})_{1 \leq u,v \leq n}$, we have

$$\sum_{v=1}^{n} a_{uv} x_v = \lambda x_u$$

with n the number of genes in the network. It turns out that λ is simply an eigenvalue of the adjacency matrix and the vector of contributions of genes is the eigenvector associated with λ.

Let $o\,(G)$ be the order, $s\,(G)$ the size of G and SP_{mean}, the mean shortest-communication from every node or gene to every destination within the network G.

Note that the cut-off of different network centrality measures are estimated using general topological properties of the network Mazandu and Mulder (2011). For the betweenness measure, the cut-off is the total number of shortest paths expected in the network, which is approximately $o(G) * SP_{mean}$. For the closeness metric, as defined above, the cut-off is $1/SP_{mean}$ and that of the degree centrality measure is the number of expected interacting genes of a gene in the network, which is $s(G)/o(G)$. In the case of the eigenvector measure, the cut-off is the mean value of the weight or contribution vector of all genes in the network.

(1) Given network G, find structural hubs and connected components;

(2) For each gene, compute the betweenness, the closeness and the eigenvector scores;

(3) For each centrality score, compute the cut-off for central genes of sub-graphs BetOf, ClosOf, DegOf and EigOf;

(4) Consider a gene as a hub if its score is greater than or equal to the corresponding cut-off;

(5) Consider a gene as a central gene if it is hub for all the four scoring measures in step (3);

(6) For each central gene, search its neighbours given a step n or the mean shortest path. The central gene and its neighbours constitute a sub-network of G.

We perform the steps above to identify sub-networks using centrality scores of each gene.

2.1.3 Multiple Correction Procedure

To account for the influence of possible type I error and account for gene/sub-network difference on the number of associated SNPs within and between studies statistics of significance, we apply a similar algorithm to the Benjamini-Hochberg Benjamini and Hochberg (1995) false-discovery correction method on their summary statistics.

(1) Rank the p-value of each gene/sub-network in order from the smallest to the largest.

(2) Multiply the largest p-value by the number of genes/sub-networks in test.

(3) Take the second largest p-value and multiply it by the total number of genes/sub-networks in gene/sub-network list divided by its rank. If less than 0.05, it is significant. Corrected p-value = p-value$*\left(\frac{n}{n-1}\right) < 0.05$, if so, gene is significant.

(4) Take the third p-value and proceed as in step 3: Corrected p-value = p-value$*\left(\frac{n}{n-2}\right) < 0.05$, if so, gene/sub-network is significant.

(5) Repeat step (1) to (4).

Below, we will discuss on how to characterize enriched sub-network given the trait ender study.

2.1.4 Characterization of enriched sub-networks

Here we aim to identify the association between sub-network (obtained from our network-based clustering approach). Let S_i, $(i = 1, \ldots, T)$ within $n_1, \ldots, n_T$ genes and human pathway $P_j \in \mathcal{P}$ be the set of human pathways. We obtained annotated pathways from Zhang et al. (2012) and collected more from annotated pathways include the KEGG, BioCarta and Ambion GeneAssist Pathway Atlas pathway databases. We downloaded genomic coordinates for all genes from the NCBI ftp-server `ftp://ftp.ncbi.nih.gov`

and retained only entries for the human reference sequence. We assign the SNPs located within a gene or less than $40kb$ distance up/downstream of the gene. Let α be the intersection between genes within S_i and genes within pathway P_j. Let β be the intersection between genes within S_i and the total genes in $P_{j,(j=1,\ldots,J)}$. Let N^* be the intersection between genes in the P_j pathway and the total genes in $P_{j,(j=1,\ldots,J)}$, and M^* be the total genes in $P_{j,(j=1,\ldots,J)}$. We compute the statistic of significance of overlap between sub-network S_i of n_t genes and a given pathway P_j using the z-score (A_S), which employs the binomial proportions test Berger et al. (2007),

$$A_S = \left(\frac{\alpha}{N^*} - \frac{\beta}{M^*}\right) \Big/ \sqrt{\frac{\frac{\beta}{M^*}\cdot\left(1-\frac{\beta}{M^*}\right)}{M^*}} \tag{S2}$$

2.2 Text S2: Evaluation of the designed method though simulation

The simulation data was generated using a simulation algorithm in HapGen2 Su et al. (2011). We simulated three independent case-control studies using CEU, YRI and MEX (see Table 1) by extraction data of chromosome 1 and 22 from HapMap3 Project Frazer and et al (2007); McVean et al. (2012).

For each datasets, we further conducted quality control to remove all structured, indel, multi-allelic variants and those with low minor allele frequency (MAF < 0.05) prior rephasing. We first phased and inferred the haplotypes using Eagle Loh et al. (2016) from the resulting curated data in Table 1. We performed a post-phasing quality control. We checked the switch-error between haplotypes panel and curated 1000 Genomes haplotypes McVean et al. (2012), 99.7%, 98.05%, 97.05% of sites were with no phase switch-error in these 3 panels (CEU, YRI an MEX), respectively. We further compared sites discordance between these haplotypes panels and independently with their original VCF file prior phasing. Only sites with phase switch error showed discrepancies in MAF, therefore were removed.

Prior to simulation, we independently expanded each haplotype panel following Rogers and Harpendings (1992) model of exponential population growth Williams (1997); Li and Stephens (2003). We implemented this model using three parameters $a_0 = 2P_0\mu$, $a_1 = 2P_1\mu$ and $\lambda = 2\mu$t where P_0 which is the population size of an initial population assuming to grow exponentially to a new population size P_1 at a time t generation back from present. The mutation rate μ, is the per-generation probability that a mutation strikes a random nucleotide along the genome. Each panel was expanded to $2,000$ haplotypes.

To simulated case-control data set from each haplotype panel, we used Hapgen2 Su et al. (2011). Hapgen2 simulator applies alternative resampling approach to simulate case/control samples. It also has the ability to simulate data for many populations. In addition, it allows the user to specify risk allele, heterozygote and homozygote relative risks. Hapgen2 simulator uses Li and Stephens (LS) model of LD Li and Stephens (2003), by considering reference panel of haplotypes say $T^P = T_1, T_2, \ldots T_P$ as input, where each haplotypes is located at B biallelic sites. The LS model takes each new haplotypes as a deficient mosiac of the haplotypes T^P. Controls are simulated by adding haplotypes under LD model and by using copy states, which are developed through Markov ways. The haplotypes are simulated into three stages. Firstly, the cross-over events (by using transition probability) mimic the effect of recombination and separate them into independent segments. Secondly, the copying state is uniformly sampled, and lastly, the allele at each SNP is conditionally simulated on the copying state and a mutation parameter. Cases are simulated in the same way, but in pairs, hence the simulation of each haplotype pair arise from four steps.

Here, we simulated $1,000$, $3,000$, 950 cases and $1,000$, $3,000$, $1,000$ controls from the haplotype (combination of multiple SNPs) data of CEU, YRI and MEX respectively. We randomly selected 3 SNPs on chromosome 1 and 3 other SNPs on chromosome region 22 to be simulated as causal disease genetic variants. The simulated disease effect size parameter of those SNPs are summarized in the Table 2 below, and are chosen to fit small effect size in some studies and strong in other versus-versa.

MEX GWAS is considered to be our main study, and YRI and CEU GWAS are studies that we would like to pool information from in order to reveal larger effects in MEX GWAS and to provide valuable information that will be useful to prioritize the most important results.

3 SUPPLEMENTARY RESULTS

3.1 Text S3: Simulation and Evaluation results

3.1.1 Single-based GWAS results

To check the association signal from our simulated data sets, we conducted Genome-Wide Association Studies (GWAS) in each case-control dataset. To this end we used EMMAX Zhou and Stephens (2012). Table 3 displays the GWAS summary statistics of our simulated diseases SNPs. As expected, we obtain very weak signal of association from SNPs simulated with small effects, particularly form MEX and YRI. We obtained significant SNPs, particularly on chromosome 22 in CEU. Using a custom script in python, we plotted the Manhattan plots to represent the p-values of both chromosome 1 and 22 of GWAS on a genomic scale (Figure 1), for each simulated case-control data set.

3.1.2 Meta-analysis based on ancMETA at gene and sub-network levels

Here we used the GWAS summary statistics, consisting of study effect sizes, its standard errors and the associated p-values from the 3 simulated case-control data sets, to perform meta-analysis at gene and sub-network level using ancMETA. Further inputs required by ancMETA include (1) pairwise weighted Protein-Protein network. If Protein-Protein network is not weighted, ancMETA may use the genotype data of the study or a reference genotype data from the population close to those under study. This will allow ancMETA to compute the pair-wise SNP-LD and use it as described in the method to derive pairwise genes correlation coefficients. These pairwise gene correlation coefficients are used as the weight of the network. (2) Pathways dataset, that provides a list of pathways and associated genes.

Given these inputs, we conducted gene- and sub-network-specific meta-analysis under ancMETA. Table 4 displays top 4 genes with overall studies p-values $\leq 1.5e-08$ and the top 4 sub-networks represented by gene hubs.

The forest plot in Figure 2 indicates convergence of effect across studies, particularly simulated causal gene *CBX7*.

Importantly, the result in Table 4 indicates a convergence of the association signal in detecting true causal variants by leveraging not only multiple small effects at gene (or sub-network) level within a study, but also effects from cross studies. By leveraging the topological properties of network in significantly breaking into clustered sub-network, ancMETA identifies causal gene *CBX7* as central hub gene of one of the top significant sub-networks across these 3 studies.

3.2 Text S4: Application to Bipolar

3.2.1 Imputation fine-mapping on 7 European Bipolar Disorder GWAS data sets

As mentioned earlier, we obtained access to 7 European Bipolar Disorder GWAS cohorts (see Table 1).

Different GWAS on BD (Table 5) have been published in the last ten years, and have revealed interesting loci for understanding better the aetiology of this disorder. The general purpose of repeated GWAS was to discover genetic markers that are robustly associated with BD, to better characterize this complex disorder.

From each GWAS data set, we conducted LD-fine mapping base on the imputation of their GWAS summary statistics using the software ImpG-Summary (`http://bogdan.bioinformatics.ucla.edu/software/impg/`). ImpG-Summary implements a GWAS Gaussian imputation of summary statistics framework that leverage the haplotype and LD from close related reference haplotypes such as the $1,000$ Genomes. It is assumed that the summary statistics consist of Z-scores (note that they are distributed with mean 0 and the variance 1, under the null model of no association. The linkage disequilibrium between the marker i and j lead to a covariance among their observed Z-scores, due to the correlation r_{ij} between the two markers. In this way, under null data, the vector V of all Z-scores at all markers, is approximately distributed ($\sim \mathcal{N}(0, \Sigma)$) as the Gaussian distribution. We independently ran ImpG-Summary to each GWAS, resulting in millions of imputed z-scores of SNPs under LD with the original SNPs in the GWAS data sets.

For each population, Manhattan plots were created using a python script. Statistical strength of association (this means -log_{10} p-value) is plotted against genomic position with 22 chromosomes in different colors. The grey horizontal line indicates the genome-wide significance threshold of p-value = 5×10^{-08}. The vertical red-dotted points describe the highly significant SNPs associated with Bipolar disorder on a specific chromosome.

For Bipolar disorder GWAS on every population considered in this analysis framework except one population, we observed that the highly significant SNPs associated with Bipolar disorder are on chromosome 3. For the Scottish, British, Norwegian and European-American populations, the below Manhattan plots (see Figure S3) highlighted almost the same significant markers that are associated with Bipolar disorder, while we observed a different pattern of the distribution of significant SNPs associated with Bipolar disorder in the Irish population.

3.2.2 Gene- and sub-network-specific meta-analysis of 7 European GWAS summary statistics

Given the typed and the fine mapped GWAS summary statistics of these 7 European populations with Bipolar disorder, we conducted gene- and sub-network meta-analysis with relevant inputs required by ancMETA. At a gene level, 7 interesting genes were significant across these 7 studies (Table 7). Among these significant genes, *AGT* is strongly significant. These genes, are known to be associated with Bipolar disorder and other psychiatric disorders.

At sub-network level, we obtained 1 single significant sub-network of witch the gene *ESR1* is the central hub. This sub-network is well connected and includes several Bipolar disorder known associated genes and the most significant finding *AGT*

To further show the cross studies pattern of effect size and level of significance, We plotted the forest plots of these 7 genes (Figures 5-6).

Chapter FOUR: DECODING THE SHARED GENETIC LANDSCAPE: UNRAVELING THE INTERSECTION OF SUICIDAL BEHAVIOR AND PSYCHIATRIC PHENOTYPES FROM THE FINNGEN BIOBANK

Summary

Suicidal behaviors, with their intricate cross-diagnostic nature, represent a formidable challenge in psychiatric research. These behaviors often intertwine with various psychiatric disorders, necessitating a deeper understanding of their shared genetic underpinnings. Our study delves into the genomic overlap between suicide and a spectrum of psychiatric phenotypes, aiming to illuminate novel avenues for treatment and prevention. We leveraged genome-wide association study (GWAS) summary statistics from the FinnGen Biobank, a rich repository of genetic data. By meticulously analyzing this extensive dataset, we identified specific psychiatric conditions that share a common genetic factor with suicide. Our findings transcend traditional diagnostic boundaries, revealing a complex interplay between suicidal behavior and the following disorders: Disturbance of Activity and Attention, Anxiety Disorders, Generalized Anxiety Disorder, Alcohol Use Disorder, Bipolar Disorder, and Depression, Post-Traumatic Stress Disorder. Cross-phenotype GWAS meta-analysis encompassing these disorders with suicide revealed at variant level 12,729 significant variants ($P < 5 \times 10^{-8}$), with 521 showing potential pleiotropy. Furthermore, our gene/subnetwork-centric meta-analysis using ancMETA unearthed 1,201 significant genes (Overall $P < 0.05$), with 53 acting as hubs within subnetworks. These hub genes were implicated in significant pathways, including Signaling by Receptor Tyrosine Kinases, Signal Transduction, Axon Guidance, Nervous System Development, and Immune System function acting as top significant. These hubs represent critical nodes in the shared biological pathways, with a potential for therapeutic targeting. Our study underscores the urgent need for integrated strategies that address suicidal behavior within the broader context of psychiatric disorders. We can forge novel therapeutic interventions and preventive measures by focusing on these shared pathways. As we decode the genetic symphony, we move closer to a future where lives are saved through precision medicine tailored to intersecting vulnerabilities.

4.1. Introduction

Suicidal behavior (SB) represents a critical public health crisis, claiming an estimated 700,000 lives annually worldwide—a mortality rate of 9.0 per 100,000 individuals [1]. This phenomenon predominantly affects the young, with the majority of suicides occurring among those aged 10–49 years [2,3]. SB's significance extends beyond its mortality statistics; it is a complex psychiatric challenge due to its diagnostic ubiquity and frequent co-occurrence with a myriad of psychiatric conditions. In the European Union, psychiatric disorders impact 38.2% of the population each year, exhibiting minimal variance across member states [4]. In Finland, mental illnesses are the leading cause of early disability retirement, with approximately 101,000 individuals granted disability pensions for psychiatric conditions in 2021 [5,6]. Globally, suicide ranks as the fourth leading cause of death among individuals aged 15 to 29 years [1]. SB's spectrum includes various behaviors, with non-suicidal self-injury (NSSI)—the intentional harm to one's body without suicidal intent—emerging as a distinct category [7]. Suicide attempts (SA), defined as nonfatal self-harm with an intent to die, are estimated to occur over 20 times more frequently than death by suicide (SD). SA, as a facet of SB, contributes significantly to disability, diminished quality of life, and economic and societal strain.

Genetic factors account for a substantial portion of SB's etiology [9], with heritability estimates ranging from 30 to 55% for suicidal ideation and 17-45% for attempts, even after adjusting for comorbid psychiatric disorders [10,11]. The genetic nexus between trauma exposure, NSSI, suicidal ideation, SA, and SD presents a complex web of interactions (Richmond et al., 2019). Genetic correlations and polygenic risk scores (PRS) have established shared heritability between SB and psychiatric disorders, with the UK Biobank (UKB) data indicating a strong genetic link with depression (rg = 0.81, [12,13]; rg = 0.86, [14]) Moreover, the concept of a "p factor" has been proposed to encapsulate a common set of genetic factors underlying the comorbidity of various psychiatric disorders, suggesting a shared genetic pathway [15,18,19].

Contemporary genomic research dissects the shared genetic risk across diseases by pinpointing variants associated with multiple disorders. This endeavor employs GWAS data alongside innovative statistical methodologies [16]. A seminal study by Lee et al. (2019) identified three core dimensions of genetic risk sharing—Neurodevelopmental, Compulsive, and Psychotic—across eight psychiatric conditions, hinting at fundamental mechanisms underlying individual disorder susceptibility [17]. Furthermore, Grotzinger et al. (2022) applied structural equation modeling via GenomicSEM to GWAS datasets, revealing four principal factors indicative of genetic vulnerability that span disease clusters [19]. This analytical approach provides invaluable insights into the genetic commonalities and specificities among psychiatric disorders within a given cohort. Despite its burgeoning application, the integration of this methodology into the study of SB remains limited.

Recent investigations by Kootbodien and colleagues (2023) have delved into the shared genetic architecture of SB and specific psychiatric disorders, including major depression, alcohol use disorder, and ADHD, within subjects from the UK Biobank [14]. These studies underscore the critical role of genomic, exomic, and gene-gene interaction analyses in timely diagnosis, management, and prognosis for patients affected by suicide, particularly those exhibiting symptoms that intersect with various psychiatric conditions. However, there remains a need to replicate and extend these findings across diverse cohorts with sufficient sample sizes.

Furthermore, investigations involving multiple phenotypes often suffer from heterogeneity due to varying ascertainment protocols, sample collection methods, measurements, genotyping platforms, and GWAS tools. This lack of harmonization results in uncoordinated GWAS summary data, potentially introducing selection biases [21]. Building upon this foundation, our study focuses on unravelling the shared genetic landscape between suicide and a broader

spectrum of psychiatric disorders. We leverage a homogeneous Finnish cohort of North European ancestry, with GWAS summary statistics sourced from FinnGen [22]. FinnGen offers the advantage of population-wide homogeneity, as biological material originates from the same population, and the summary statistics adhere to a consistent protocol. Our GWAS analysis within the FinnGen cohort employs the conventional FinnGen pipeline, which effectively addresses sample relatedness and case-control imbalance using the Linear Mixed Model algorithm implemented in SAIGE [20].
Our primary objective is to identify disorder-specific components that share a common genetic factor with suicide. To achieve this, we employ the Genomic Structural Equation Modeling (GenomicSEM) technique. Subsequently, we delve into potential loci and functional enrichment associated with the gene set derived from this common factor.

The psychiatric disorders investigated in our study, listed alphabetically, include:
Disturbance of Activity and Attention (ADHD); Anxiety Disorders (ANX); Alcohol Use Disorder-ICD-based (AUD); Autism (AUT); Bipolar Disorder (BIP); Depression (DEP); General Anxiety Disorder (GAD); Neurotic, Stress-related, and Somatoform Disorders (NEU); Obsessive-Compulsive Disorder (OCD); Post-Traumatic Stress Disorder (PTSD); Suicide or other Intentional Self-harm (SUIC); Schizoaffective Disorder (SCZAF); Schizophrenia (SCZ). By dissecting the genetic architecture underlying these conditions, we aim to shed light on shared biological pathways and potential therapeutic targets.

4.2 MATERIALS AND METHODS

4.2.1 GWAS Summary Datasets

We obtained GWAS summary statistics pertaining to Disturbance of Activity and Attention (ADHD), Anxiety Disorders (ANX), Alcohol Use Disorder-ICD-based (AUD), Autism (AUT), Bipolar Disorder (BIP), Depression (DEP), General Anxiety Disorder (GAD), Neurotic, Stress-related and Somatoform Disorders (NEU), Obsessive-Compulsive disorder (OCD), Post-Traumatic Stress Disorder (PTSD), Suicide or other Intentional self-harm (SUIC), Schizoaffective Disorder (SCZAF), and Schizophrenia (SCZ) from the FinnGen database. **Table 4.1** presents a summary of the data used in this study; for further information about data collection methods and techniques, please refer to the original publication [22].

Table 4.1 Summary information of the phenotypes of our study from the FinnGen Biobank

Phenotype	**#Case**	**#Controls**	**Sample size**	**Number of SNPs**
SCZAF	2,518	297,496	300,014	16,383,306
SCZ	6,050	297,496	303,546	16,383,311
BIP	5,763	271,380	277,143	16,383,274
DEP	33,812	271,380	305,192	16,383,312
NEU	30,336	278,818	309,154	16,383,316
ANX	30,731	278,423	309,154	16,383,316

AUT	418	306,261	306,679	16,383,316
AUD	14,307	328,192	342,499	20,169,557
ADHD	1,357	304,758	306,115	16,383,302
GAD	3.228	278,818	282,046	16,383,246
OCD	1,466	278,818	280,284	16,383,236
PTSD	1,639	278,818	280,457	16,383,235
SUIC	1361	341,138	342,499	20,169,557

After the data was retrieved from the FinnGen database, we initiated a thorough process of data refinement. First, duplicate SNPs were eliminated, and we extracted SNPs that had a Minor Allele Frequency (MAF) greater than 0.01. We also eliminated SNPs that had conflicting alleles and those that had missing information from the Genome-Wide Association Study (GWAS) summary statistics for each disorder.

4.2.2. SNP-Based Heritability and Genome-Wide Genetic Correlation

Our study used univariate LD-score regression (LDSC) [23] to measure the portion of phenotypic variance due to common genetic variants, known as SNP-based heritability (h^2 SNP) in the observed scale. The method was implemented using the GenomicSEM R package [18] and adhered to default settings for quality control processes. The Major Histocompatibility Complex region, characterized by a complex gene network, often contains SNPs with large effect sizes, requiring exclusion to prevent skewing results. LD scores were derived from the 1000 Genomes European sample, limited to HapMap3 SNPs for reliable heritability and genetic correlation estimates. The default settings were followed in the quality control processes for genetic covariance and sampling covariance matrices.

4.2.3. Genomic Structural Equation Modelling Analysis

Genomic factor analysis was performed using the R package, GenomicSEM. We assume that the underlying latent structure of genetic variance between traits was unknown. Initially, we performed a genomic exploratory factor analysis (EFA) to determine the number of factors that best describe the shared genetic variation; next, we applied this to inform the subsequent genomic confirmatory factor analysis (CFA) to estimate the parameter for model fitting. EFA allowed us to detect different number of factors to identify which model performed best using predefined criteria. Since diagonally weighted least squares estimation takes into account variations in GWAS sample size and is more accurate when modelling trait characteristics (Grotzinger et al., 2019), we implemented it to run all the models. We compared the outcomes of the fitting models test following previously suggested cut-off values for genomicSEM in order to evaluate the fit of the various models from CFA. We used the following as measures for absolute fit: AIC (Akaike Information Criterion), a measure used to compare the quality of statistical models, with lower values indicating a better fit. The standardized root mean square residual (SRMR) with values ≤ 0.10 indicating moderate fit, and SRMR ≤ 0.05 indicating good fit; the comparative fit index (CFI) test with values ≥ 0.90 (indicating moderate fit) and CFI $\geq$ 0.95 (indicating good fit). Additionally, we examined the chi-square statistics, which indicate a precise match, and where lower chi-square values correspond with greater fit [18].

4.2.4. Variant-based GWAS Meta-analysis on the Revised Common Factor

We performed a variant-based GWAS cross-trait meta-analysis on the revised common factor to pinpoint potential pleiotropic variants/SNPs cross-associated with the disorders of the revised common factor. Characterizing the functional genomics of cross-phenotype genetic effects may also assist in finding targets for diagnostics and treatments by illuminating the basic characteristics of pleiotropic loci that set them apart from loci unique to a particular disorder. We deployed RE2C (v1.06) [24], which accounts for sample overlap among GWAS summary data (http://software.buhmhan.com/RE2C) to perform the analysis. RE2C* *P*-value, which is conditioned for the overlapping samples was used as the significance level for each variant. SNPs and loci that were significant (RE2C*$P < 5 \times 10^{-8}$) after meta-analysis but were not genome-wide significant in either of the individual trait GWAS datasets were regarded as novel [25]. In addition to the fixed effect (FE) and the modified random effects (RE2) models [26], we conducted cross-trait GWAS meta-analyses which were integrated into the METASOFT software (http://genetics.cs.ucla.edu/meta/). To estimate the SNP meta-analysis statistics (effect size and p-value), the FE model, supposing that the GWAS traits examined the same (fixed) effect, employed the inverse variance weighted technique. In the presence of heterogeneity based on the I^2 statistics METASOFT makes use of the random effects (RE2) model to estimate the SNP meta-analysis statistics, using the METASOFT m-value technique [27]. The m-value is the cross-trait meta-posterior analysis probability that the effect occurs in each trait [27]. METASOFT was also utilized to identify potential pleiotropic loci based on the m-value. M-values larger than 0.9 denote the presence of the effect or rather the contribution of the joint effect of a SNP from all participating studies implicating evidence of pleiotropy across the disorders. M-values less than 0.1 denote the absence of the effect, and m-values between 0.1 and 0.9 suggest ambiguity regarding the presence of the effect.

4.2.5. Gene and Subnetwork-Specific Meta-Analysis of the Revised Common Factor

Gene and subnetwork-specific meta-analysis was performed using ancMETA [28] to estimate the aggregated genetic effects of variants nearby genes and the level of significance of the revised common factor (refer to **Figure 4.4**). Common SNPs were extracted from all studies and mapped to genes located within or less than 20 kb distance up/downstream of the protein-coding gene using FUMA SNP2GENE option [29]. ancMETA, based on common SNPs mapped to genes, deploys a Bayesian posterior probability approach, merges the data into datasets of known biological protein-protein networks, conducts meta-analysis at the gene and sub-network levels, and finds the most significant sub-network hubs to map the biological pathways. The expression level and tissue enrichment of the identified hub genes were investigated using FUMA from the GENE2FUNC option [29]. The most recent version of the human protein-protein interactions (PPI) network from the STRINGv11 database [30] was used to generate the network encompassing all the significant hub genes. The list of significant hub genes within the network was plugged into Enrichr (https://maayanlab.cloud/Enrichr/) to identify the underlying pathways and biological processes contributing to the common factor. Additionally, The Drug-Gene Interaction Database v4.0 (DGIdb 4.0), an open-access database and web interface, was used to identify drug-gene interactions (https://beta.dgidb.org/). DGIdb gathers drug-gene interaction and druggable gene data from 30 different sources and 22 databases [31].

4.3. Results

4.3.1 SNP-Based Heritability and Genome-Wide Genetic Correlation

The FinnGen cohort demonstrated overall low estimates of SNP-based heritability for the thirteen disorders on the observed scale with the lowest being AUT (h_2 = 0.0071, SE = 0.0125) and the highest being GAD (h_2 = 0.0786, SE = 0.0173) (**see Table S1A-B**). Given this evidence of SNP-based heritability across all of these traits, we employed bivariate LDSC to investigate genetic correlations between them. After correction for multiple testing (p = 0.05/13 = 0.0038), strong significant genetic correlations were observed between ANX and DEP (rg = 0.9278; p-value = 1.03×10^{-45}), followed by DEP and NEU (rg = 0.9266; p-value = 1.97×10^{-44}) and between ANX and NEU (rg = 1.0004; p-value = 3.85×10^{-38}). There was evidence of significant genetic correlation between ANX and AUD (rg = 0.67; p-value = 3.83×10^{-33}), NEU and AUD (rg = 0.67; p-value = 1.4×10^{-32}), DEP and AUD (rg = 0.6686; p-value = 2.15×10^{-32}). Significant positive genetic correlation was detected between DEP and SUIC (rg = 0.94; p-value = 5.5×10^{-12}), AUD and SUIC (rg = 0.73; p-value = 8.39×10^{-08}), NEU and SUIC (rg = 0.71; p-value = 3.09×10^{-07}), ANX and SUIC (rg = 0.72; p-value = 3.24×10^{-07}), PTSD and SUIC (rg = 1.24; p-value = 0.0007), BIP and SUIC (rg = 0.59; p-value = 0.0017)(**Figure 4.1**). This figure **(Figure 4.1**) illustrates that, at least within the FinnGen cohort, genetic components associated with one disorder strongly increase the risk of symptoms of the other. This is particularly likely for SUIC which exhibits a high and significant positive correlation with PTSD and DEP.

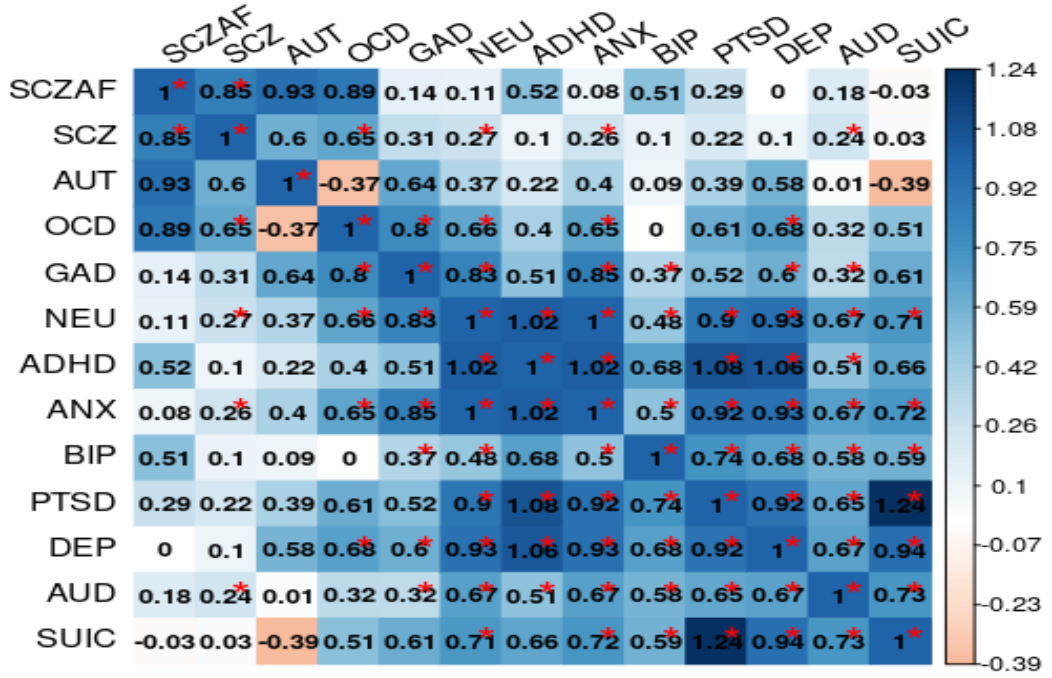

Figure 4.1. Pairwise genetic correlation heatmap between the thirteen disorders within the FinnGen Biobank. The red star (*) highlights the significant correlation, after Bonferroni correction.

4.3.2 Genomic Structural Equation Modelling Analysis

First, we ascertained the level of common genetic variance between all of the included traits by testing the performance level of a common genetic factor. The common factor model, with freely determined loadings, had a fair fit (chi-square, $X^2(65) = 95330.87$, AIC = 95382.87, CFI = 0.993, SRMR = 0.147) (**Figure 4.2A**). Next, our GenomicSEM analyses identified an acceptable fit of a strongly correlated two-factor model, which was able to fit the data best (chi-square, $X^2(26) = 13167.04$, AIC = 13205.04, CFI = 0.9986, SRMR = 0.0585) suggesting that the shared molecular mechanism increasing the risk of the comorbidity factor F_2 correlates with the one included in F_3 (**Figure 4.2B**).

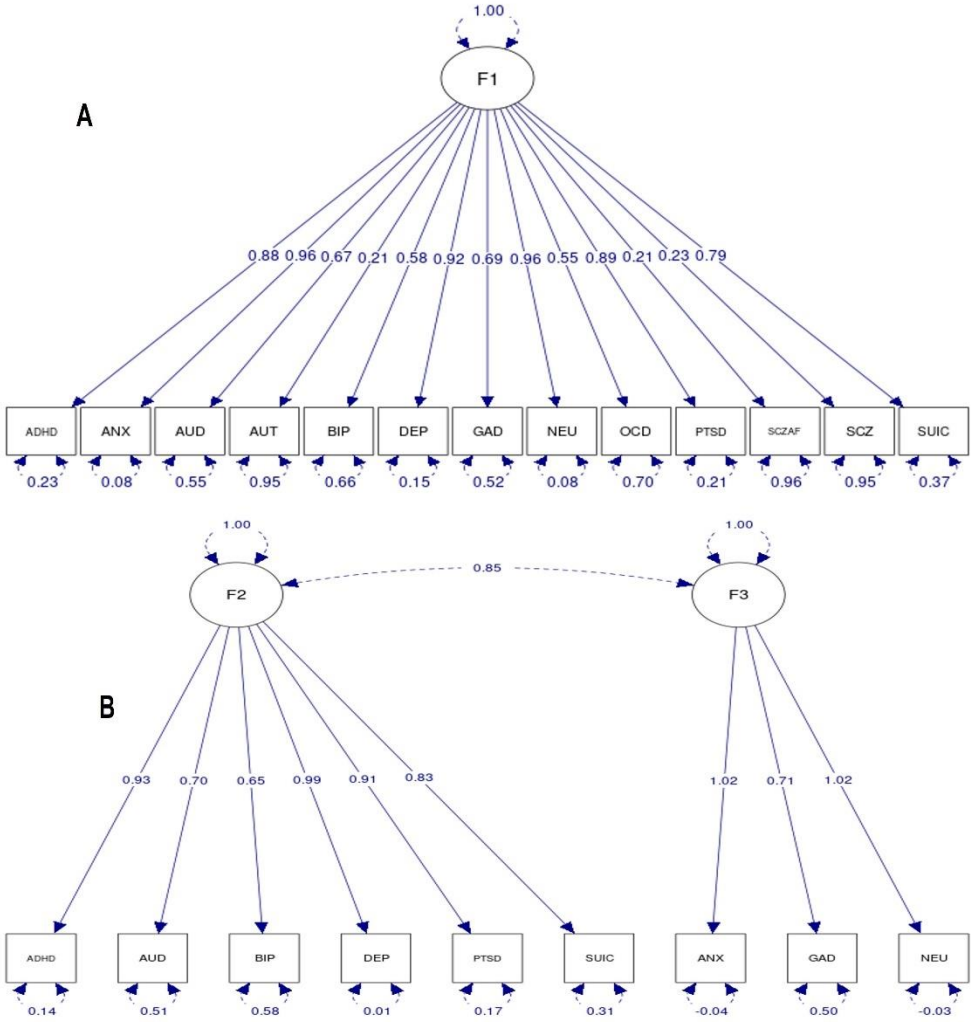

Figure 4.2. **A**- Path diagram for the single common factor model, which shows the overall common variance among all included traits. Path diagrams in GenomicSEM use squares to represent seen variables and circles to represent unobserved, or latent, variables. One-headed arrows going from the independent variable to the dependent variable are used to illustrate regression connections between variables. A two-headed arrow connecting a variable to itself is used to symbolize the variance of a variable or the covariance between a variable and itself; **B**- Path diagram for the two common factor model. Two-headed arrows connecting two variables indicate covariance connections between them. The figure shows the strong correlation between the factors; with SUIC sharing the same factor with ADHD, AUD, BIP,

DEP, and PTSD. This factor is strongly correlated with the factor encompassing ANX, GAD and NEU.

In addition to the above, we identified two different correlated factor scenarios encompassing most of the observed disorders. The first scenario highlights two positive correlated factors similar to that in **Figure 4.2B**, however with SCZAF, SCZ and OCD sharing each of these factors (see **Figure 4.3A**). This model fits the data best with good estimates (chi-square, X2(47) = 8602.041, AIC = 8664.041 CFI = 0.99925, SRMR = 0.077). The second scenario similar to **Figure 4.3A**, is shown with the addition of AUT as the common factor of all the observed traits. The model generated best fit estimates (chi-square, X2(47) = 10562.07, AIC = 10650.07 CFI = 0.999, SRMR = 0.071) (**Figure 4.3B**). This was followed by an investigation of a three-factor model fit with a factor loading score > 0.3. The model accounts for 80% cumulative variances. The model fits best (chi-square, X2(47) = 20150.97, AIC = 20238.97 CFI = 0.99855, **SRMR = 0.0708**), assuming a correlation between the factors, and with AUT inter-correlated between the factors (**Figure 4.3C**). The first factor includes ANX, GAD, NEU, ADHD, AUD, DEP and OCD; the second factor includes ADHD, AUD, DEP, BIP, PTSD and SUIC, and the third includes OCD, SCZAF and SCZ.

It is worth mentioning that, through the process of building the model, a constant common factor with constant fit estimates was identified (based on the assumption of a common 'revised factor' underlying or underpinning the three-factor model) which included ADHD, ANX, AUD, DEP, BIP, GAD, PTSD and SUIC. Interestingly, this set of phenotypes shows a constant common factor model with good estimates regardless of the model being fitted (chi-square, X2(20) = 38.7, P_{chisq} = 0.007, AIC = 70.7, CFI = 0.99, SRMR = **0.071**) suggesting that these eight disorders establish a firm constant common factor in the FinnGen cohort (**Figure 4.4**).

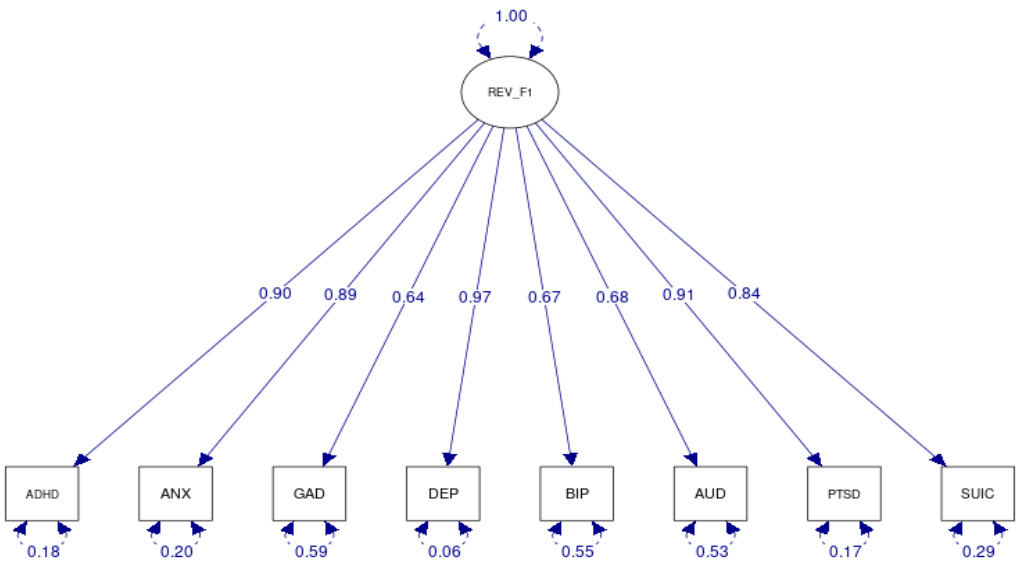

Figure 4.4. Path Diagram of the Revised constant common factor encompassing ADHD, ANX, DEP, BIP, AUD, GAD, PTSD and SUIC.

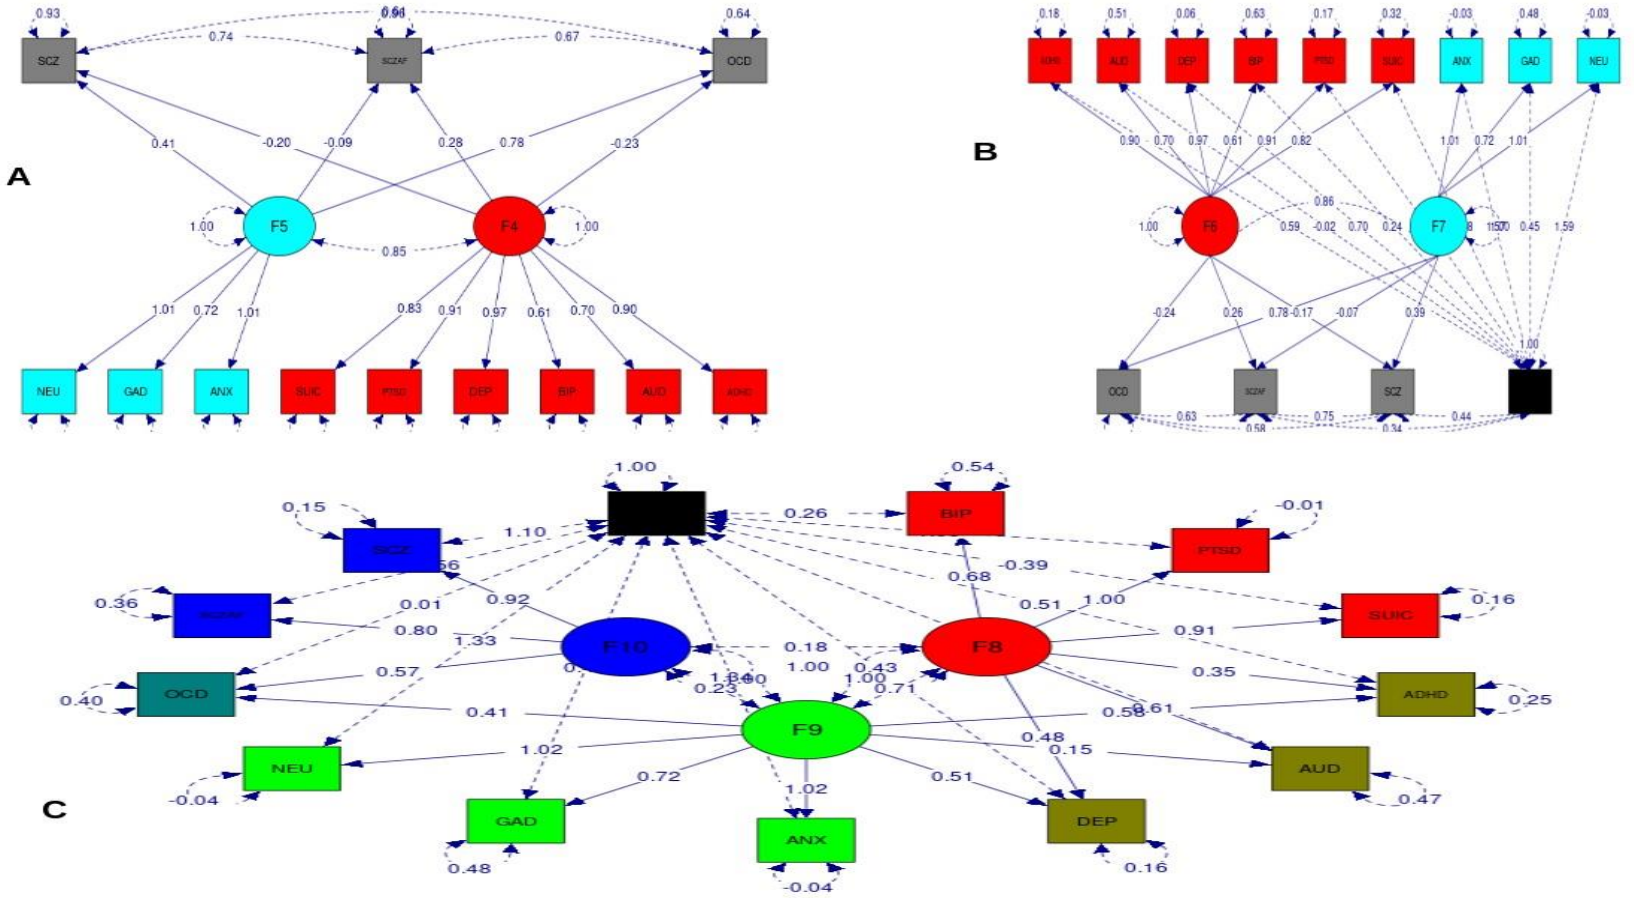

Figure 4.3. **A**- Path diagram for the revised correlated two-factor model without AUT; **B**- Path diagram for the revised correlated two-factor model including AUT (in black). The figure exhibits how AUT could be considered the common factor of the rest of the observed traits; **C**- Path diagram for the three-factor model. The figure shows a positive correlation between factors and AUT (in black) as the common factor of each of the observed traits/phenotypes.

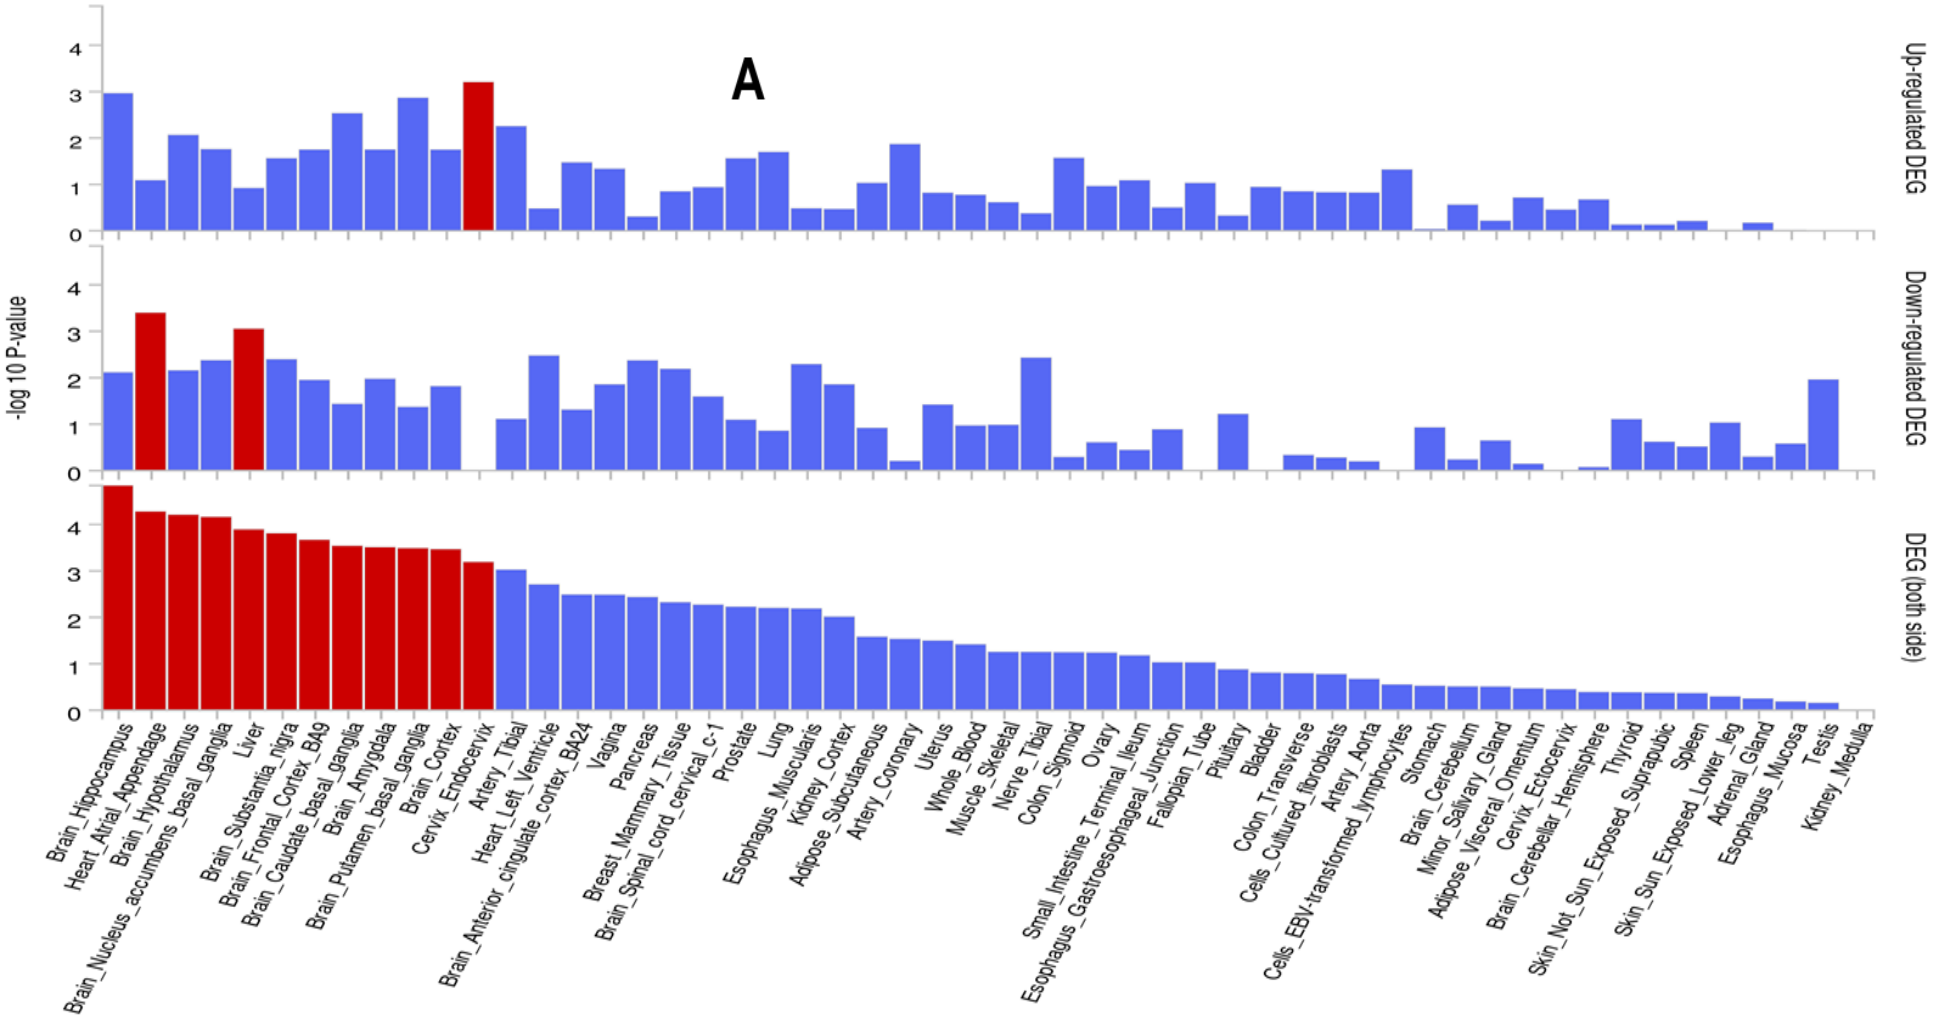
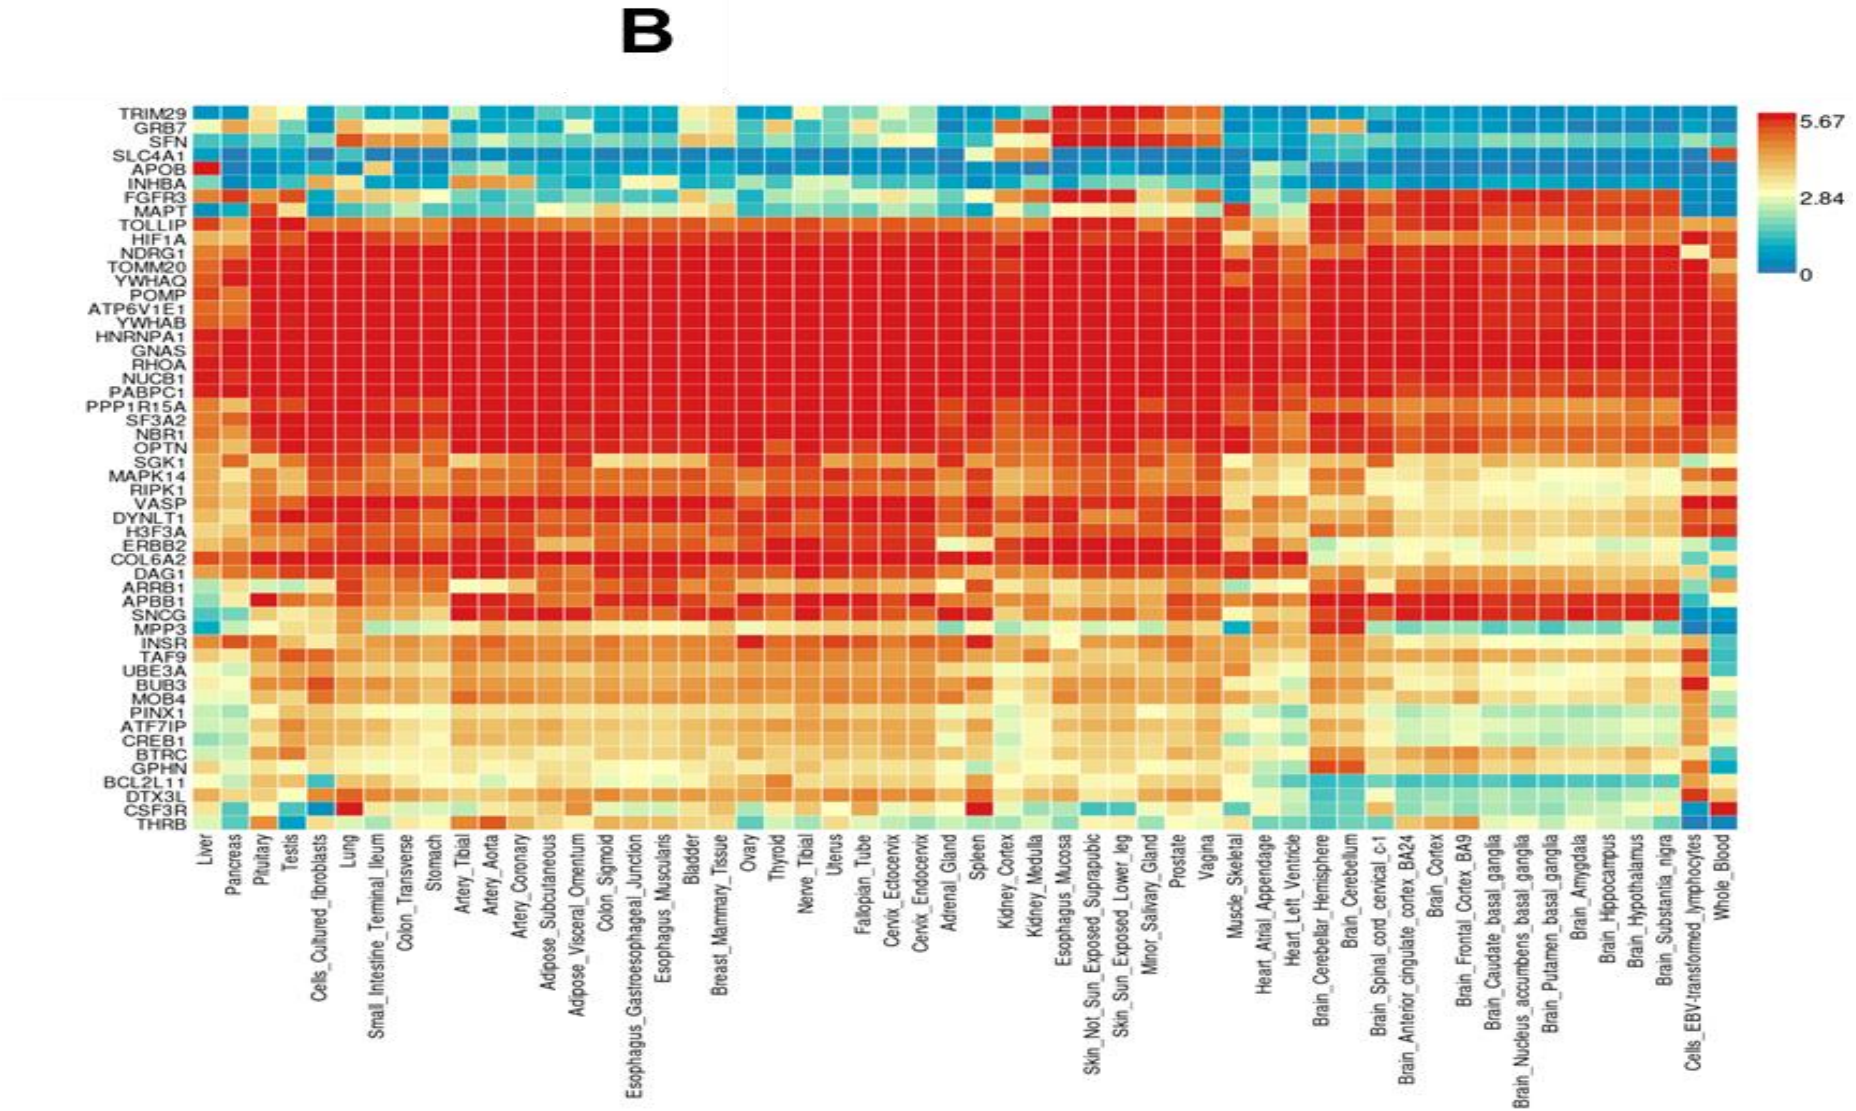
Figure 4.3. **A**- Path diagram for the revised correlated two-factor model without AUT; **B**- Path diagram for the revised correlated two-factor model including AUT (in black). The figure exhibits how AUT could be considered as the common factor of the rest of the observed traits; **C**- Path diagram for the three-factor model. The figure shows a positive correlation between factors and AUT (in black) as the common factor of each of the observed traits/phenotypes.

4.3.3. GWAS Meta-analysis on the disorders encompassing the Revised Common Factor

Because SUIC seems to originate from the same common factor as ADHD, ANX, AUD, BIP, DEP, GAD, and PTSD, we sought to ascertain the shared loci or molecular mechanism underlying the revised common factor encompassing these disorders. To identify shared genetic components on the revised common factor, we first performed cross-disorder GWAS meta-analysis at variant level to discover the association of putative SNPs, and thereafter, accounting for the aggregation of variants within proximal genes from each GWAS summary, performed gene and sub-network meta-analyses to identify potential genes, pathways and networks of genes underlying the shared mechanism between traits included in the revised common factor. We then interrogated the biological significance of the identified associations by performing a functional enrichment analysis of the hub genes. The result of the analyses lends insight into genetic relationships and the shared mechanism between these traits.



4.3.3.1. Variant-based GWAS Meta-analysis on the Revised Common Factor



Our cross-trait meta-analysis using RE2C identified 12,729 significant variants (RE2C*$P < 5\times10^{-8}$) (**Table S2**) with overall small to moderate effects. Among these significant SNPs, 521 potential pleiotropic variants were identified (m-value > 0.9 for all disorders) indicating the probability of each SNP affecting all of the disorders (**Tables S3 and S4**). The top five significant pleiotropic variants were located near genes *PRR16, BTN3A2, POM121L2, ZNF322,* and *ZNF184* (**Table 4.2, Tables S2-S4**). Among the list of our potential pleiotropic variants, *PRR20A, SMYD3, PCDH10, MON1B, SLC17A2, MRPL33, PTPRD, BTN3A1, ZNF184, HIST1H2BJ, PITRM1, and ANKRD1* are the top nearby genes containing a significant number (more than 10) of potential pleiotropic variants.

Table 4.2. Top five significant potential pleiotropic loci (m-value > 0.9) from the cross-phenotype GWAS meta-analysis encompassing disorders part of the revised common factor.

Figure 4.5. (**A**)- Baplot of tissue-expression enrichment of genes from significant pleiotropic SNPs. The colour Red suggests the enrichment/significance of the tissue while blue suggests the non-enrichment/significance of the tissue; (**B**)- Heatmap of the gene expression from the pleiotropic SNPs; (**C**)- Genemania network interface showcasing the variety of interactions between the genes proximal to the associated pleiotropic SNPs.

Using the GENE2FUNC option in FUMA [29], we investigated the expression level and tissue enrichment of the genes proximal to the identified pleiotropic loci. The results suggest that genes emerging from the significant pleiotropic loci were differentially expressed in several central nervous system tissues. Notably, the strongest enrichment was observed for genes expressed in the hippocampus, hypothalamus, nucleus accumbens, substantia nigra, frontal cortex, caudate, amygdala, putamen and the cortex (**Figures 4.5A and 4.5B**) indicating that this enrichment was exclusive to subcortical and limbic structures. Particularly, down-regulated genes were evident in non-brain tissues which include the heart and liver which have been suggested to be tissues with somatic and endocrine functions.

4.3.3.2. Gene and Subnetwork-Specific Meta-Analysis of the Revised Common Factor

ancMETA identified 1,201 significant genes (overall P < 0.05) (**Table S5**) with *PPM1G* (p-value = 2.17×10^{-05}), *LRBA* (p-value = 2.299×10^{-05}), and *BSN* (p-value = 4.78×10^{-05}), being the top three (**Table 4.3**). The data indicates that the combined impact of these genetic variations within specific genes significantly aligns at the gene level, contributing to the association across multiple phenotypes with disorders linked by a common factor. *PPM1G* is associated with impulsivity and behavioural disinhibition, which are features of several mental health disorders, including AUD and suicidal ideation [32]. This gene was associated with SB when carrying loss-of-function mutations [33]. In a previous study, *LRBA* was identified as an autism-related candidate gene [34]; while *BSN* has previously been linked to SCZ [35], and SCZAF via GABA signalling [36].

Table 4.3. Top 3 significant genes and subnetwork hub genes from the cross-trait meta-analysis of disorders included in the revised common factor.

Gene	#Study	Overall P	Q	Tau^2	P_SUIC	P_BIPO	P_ADHD	P_DEP	P_ANX	P_PTSD	P_GAD	P_AUD

Q: level of heterogeneity in the meta-analysis testing whether studies shared the common effect size; tau^2: variance of the effect size of each gene across the studies.

At subnetwork level, ancMETA identified 721 hub genes amongst which 53 were significant (overall P < 0.05) (**Table S6**). Among the latter hub genes, *GPHN* (p-value = 6.719×10^{-05}), *MAPT* (p-value = 4.3×10^{-04}), and *RHOA* (p-value = 5.06×10^{-04}) were the most significant

(**Table 4.3**). This observation indicates that the accumulation and impact of genetic variants within these hub genes significantly converge at the pathway or gene set level, contributing to the cross-phenotype association with disorders implicated in the common factor.

Results suggest that the set of hub genes was differentially expressed in the pancreas, and brain tissue (**Figure 4.6C**). The most significant enrichment in the brain was observed for hub genes in the brain cortex, the nucleus accumbens, the anterior cingulate cortex, and the putamen basal ganglia. The cerebellar hemisphere showed significance exclusively for down-regulated differentially expressed genes.
The interactions between the hub genes from ancMETA were visually depicted in **Figures 4.6A** and **4.6B** using significant hub genes. The network from Genemania [66] exhibits the lines connecting the circles suggesting a mix of genetic interactions, co-expression, and co-localization. It suggests that these genes may be cooperating and interacting with each other. Potentially strong interactions between hub genes were depicted in the Genemania graphic, both directly and indirectly through other genes.

Figure 4.6. **(A)-** Protein-Protein Interaction Network from STRING encompassing all the identified significant hub genes generated by ancMETA; **(B)-** Outcome from GeneMANIA based on significant hub genes. The genes from the top hit GWAS are shown as larger circles, while genes from the GeneMANIA extension are smaller; **(C)-** Baplot of tissue-expression enrichment of significant hub genes. The colour Red suggests the enrichment/significance of the tissue while blue suggests the non-enrichment/significance of the tissue**.**

With the set of significant hub genes, 93 significant Reactome pathways, 56 significant KEGG pathways and 101 significant WikiPathways underlying the shared risk of the disorders implicated in the common factor were identified (adjusted p-value < 0.05) (**Tables S7-S9**). PI3K-Akt-signaling pathway (adjusted p-value = 4.8×10^{-06}), Rap1-signaling pathway (Adjusted p-value = 0.0017), MAPK-signaling pathway (adjusted p-value = 0.0058), and Aldosterone-regulated sodium reabsorption (adjusted p-value = 0.0058) were most significant according to KEGG. Signaling by Receptor Tyrosine Kinases (adjusted p-value = 1.97×10^{-07}), Signal Transduction (Adjusted p-value = 4.23×10^{-06}), Axon Guidance (adjusted p-value = 1.5×10^{-04}), Nervous System Development (adjusted p-value = 1.78×10^{-04}), and Immune System (adjusted p-value = 6.1×10^{-04}) were the most significant pathways/biological processes, according to Reactome. The Orexin Receptor Pathway (adjusted p-value = 9.66×10^{-07}), Leukocyte Intrinsic Hippo Pathway Functions (adjusted p-value = 2.83×10^{-04}), and Myometrial Relaxation and Contraction Pathways (adjusted p-value = 3.46×10^{-04}) were the most significant according to WikiPathways.
Our analysis reports that the top significantly enriched biological processes from our list of significant hub genes include Negative Regulation of Transferase Activity (adjusted p-value = 0.0026), DNA Damage Response (adjusted p-value = 0.0034), and Negative Regulation Of Protein Ubiquitination (adjusted p-value = 0.004) (**Table S10**). Furthermore, the top enriched molecular functions encompassing the hub genes in the network include Transmembrane Receptor Protein Tyrosine Kinase Activity, Insulin-Like Growth Factor Receptor Binding, and Ubiquitin-Like Protein Ligase Binding (**Table S11**). Likewise, Focal Adhesion, Cell-Substrate Junction, and Cytoplasmic Vesicle Membrane were the top enriched cellular components from the significant subnetwork hub genes (**Table S12**). All these molecular and cellular mechanisms confer stress-induced social behaviour and interaction changes which, if not controlled, may promote neuronal cell death or apoptosis.

4.3.4. Drug-gene interactions

Using the DGIdb database to investigate drug-gene interaction of the 53 significant hub genes suggested by ancMETA led to the identification of 1129 potential drugs, including 326 already approved with known interaction types. The information about the source and interaction type of target drugs is provided in the **Table S13**. Among the hub genes listed, 20 were druggable, and 16 were clinically actionable (**Table S14**). The final list only included drugs approved by the USA Food and Drug Administration, with several drugs already tested in clinical trials. Some of these identified drugs include Quercetin, Daunorubicin, Doxorubicin Hydrochloride, Tretinoin, and Cytarabine, amongst many others (**Table S13**). These drugs have been studied in clinical trials, including their efficacy relating to phenotypic traits.

4.4. DISCUSSION

In this study, we examined the common genetic architecture between psychiatric disorders and SB using large-scale GWAS summary-level data from the FinnGen Biobank. We found significant positive genetic correlations between SUIC and several psychiatric disorders, including depression (DEP), alcohol use disorder (AUD), neuroticism (NEU), anxiety (ANX), post-traumatic stress disorder (PTSD), and bipolar disorder (BIP). Our GenomicSEM analysis identified disorder-specific components that share a common factor with SUIC, including ADHD, ANX, AUD, BIP, DEP, GAD, and PTSD, suggesting the existence of shared genetic variation at the variant, gene, and/or molecular mechanism level.

These findings suggest a disorder-specific network having a common factor encompassing SUIC with a set of psychiatric disorders including ADHD, ANX, AUD, DEP, BIP, GAD, and PTSD confirming previous work, including epidemiological [37,38,39] and/or genomic findings [40,41,14]. Particularly, this finding expands the one conducted by Kootbodien and colleagues (2023) adding PTSD, ANX, GAD and BIP to the list of disorders sharing a common factor with SUIC. Furthermore, this finding has potential implications in the comorbidity of diagnoses, knowing that most individuals with SUIC have a or several psychiatric diagnoses. The list of disorder-specific components sharing the same common factor may suggest a comorbid manifestation in terms of psychiatric-related phenotype manifestation.

Our cross-phenotype GWAS meta-analysis singled out 521 pleiotropic variants with signals proximal to *PRR16, BTN3A2, POM121L2, ZNF322,* and *ZNF184* being the strongest. *PRR16* was identified in a previous GWAS meta-analysis of DEP [42]. The potential pleiotropic genes are widely expressed in different brain tissues; some at relatively high levels, which suggest that these genes could be considered as candidates for drug targets. *BTN3A2*, with other Butyrophilin family interactions (*BTN3A1, BTN3A3, BTN2A2, BTN2A1, BTN1A1*) include significant pleiotropic variants. This family of genes, based on a co-expression network approach, are associated with DEP [43]. Lin et al (2021) also reported an association between several genes of this family, and both DEP and insomnia [44]. *POM121L2* has been previously associated with SB in a European-ancestry-specific GWAS meta-analysis [45]. Little is known about the function of *POM121L2*; however, one study has detected variants in this gene/locus linked to suicidal ideation, conditioned on comorbid conditions including Insomnia, PTSD, SCZ, BIP and DEP [46]. Furthermore, the differential expression of *ZNF184* was strongest in subcortical regions in males and females with DEP [47, 48]. *ZNF184* was also associated with BIP [49, 50].

Our gene- and sub-network-specific meta-analysis encompassing the trait included in the revised common factor revealed 1,201 significant genes with *PPM1G, LRBA*, and *BSN* as the top significant. The same analysis unearthed 53 significant sub-network hub genes with *GPHN, MAPT,* and *RHOA* as top significant. A previous study identified variants within *GPHN* (the gene encoding the inhibitory synaptic scaffolding molecule, gephyrin) associated with suicide attempts in individuals with DEP [51]. Moreover, uncommon copy number variants within *GPHN* have been found in several individuals with other neurodevelopmental disorders, such as AUT-spectrum disorder, SCZ, and seizures [52, 53]. *MAPT* has been linked as a shared risk gene between frontotemporal dementia and SCZ using cis-expression quantitative trait loci analysis [54]. *RHOA* is a member of the RAS homolog (Rho) family and, through Rho-kinase, is involved in the development, survival, and plasticity of the central nervous system [55]. Previous studies have shown that mRNA expression levels of *RHOA* are altered in SCZ [56]. Moreover, Lin et al. (2021) reported *RHOA* associated with DEP and insomnia [57]. According to Reactome these three hub genes, amongst others, showed significant enrichment in the functioning of the immune system, development of the nervous system, signaling by Receptor

Tyrosine Kinases and signal transduction processes. These pathways were confirmed by previous studies [41, 14].
Our study reveals that the potential pleiotropic loci are significantly expressed in the brain, particularly in the hippocampus, hypothalamus, nucleus accumbens, basal ganglia, substantia nigra, frontal cortex, caudate, amygdala, and cortex. Meanwhile, by aggregating variants within genes accounting for protein-protein interactions, the significant hub genes that we detected were enriched for expression in the brain cortex, nucleus accumbens, basal ganglia, the anterior cingulate cortex, and putamen_basal ganglia (from the results generated by FUMA). This finding corroborates prior functional neuroimaging investigations, indicating that individuals with a shared history of suicide and psychiatric disorders associated with the revised common factor may exhibit anomalies in multiple brain regions responsible for regulating emotions, making decisions, and controlling impulses. This is characterized by a diminished ability to regulate motivational responses to significant negative stimuli. [58, 59, 60, 61, 62, 63].
Our study contributes to elucidating this shared architecture within the FinnGen Biobank. Genetic variants with high pleiotropy are typically associated with genes expressed across various tissues, suggesting that pleiotropy may arise from the co-expression and co-regulation of proximal genes, potentially affecting diverse physiological processes [64]. This hypothesis was supported in our study, where we identified 521 potential pleiotropic variants showing a high level of co-expression among nearby genes. These genes were notably expressed in brain regions including the cortex, nucleus accumbens, anterior cingulate cortex, and putamen basal ganglia.

Given that most disease phenotypes result from complex interactions among multiple genes, we employed a network-guided strategy. Genetic variants influence gene products whose activity and expression are regulated within intricate molecular networks in cells, potentially propagating their effects through various regulatory pathways [65]. Using this approach, we conducted gene- and sub-network-specific genome-wide association meta-analyses, which helped identify potential gene-enriched pathways and shared Gene Ontology terms between SUIC and psychiatric disorders within the FinnGen cohort.

However, our study has several limitations. It focused on individuals of European ancestry, thus limiting generalizability to non-European populations. Additionally, SB in our cohort was classified based on self-reported items or cases identified through hospital inpatient and death registry ICD-10 coding, potentially leading to underreporting and misclassification bias. Furthermore, despite including various genetic risk factors, the GWAS approach has inherent limitations, including the need for larger sample sizes to ensure reproducibility. Additionally, due to the lack of sex-specific GWAS summary datasets for all traits, we were unable to explore sex-specific effects, despite known sex differences in the heritability of psychiatric disorders [69] and suicidal individuals [67, 68].

It is important to note that our study design does not include environmental factors. This is one caveat identified in our analysis as a possibility that unmeasured/unaccounted-for environmental factors, including things like infection with viral diseases, could have acted to increase the expression of the inflammatory-related gene signatures. However, the chapter we are dealing with here is limited to the shared genetic aspect and not the full spectrum which may include environmental causes of the up-regulation of inflammatory signatures in those with suicide.

In conclusion, we depicted a shared genetic architecture contributing to the development of SB and a cluster of psychiatric illnesses, sharing a common neurodevelopmental origin. Our study

contributes to elucidating this shared architecture within the FinnGen Biobank. Moreover, this study may facilitate the identification of relevant biomarkers and, in conjunction with therapeutic and environmental factors, improve diagnosis, treatment, and prevention of suicide with psychiatric symptoms.

Chapter FIVE: UNRAVELLING THE SHARED GENETIC ARCHITECTURE BETWEEN SUICIDALITY AND SUBCORTICAL BRAIN VOLUME: A GENOME-WIDE ASSOCIATION STUDY

This chapter has been accepted in *Acta Neuropsychiatrica.*
Defo, J., & Ramesar, R. (2024). Unravelling The Shared Genetic Architecture Between Suicidality and Subcortical Brain Volume: A Genome-Wide Association Study. (Accepted in *Acta Neuropsychiatrica*).

Summary

Suicidality represents a critical public health challenge with complex neurobiological underpinnings. Recent neuroimaging and genetic studies indicate pathological brain volumetric abnormalities in individuals exhibiting suicidal behaviours and in post-mortem brain samples from suicide victims. Despite advances in understanding the genetics of suicidality, the shared genetic architecture between suicidality and subcortical brain volumes remains obscure.
Our study leverages Genome-Wide Association Studies (GWAS) to investigate the genetic overlap between suicidality and subcortical brain volumes. We obtained summary statistics from suicidal behaviour measures—including Suicide Attempts (n = 50,264), Ever-Self Harmed (n = 117,733), and Thoughts of Life Not Worth Living (n = 117,291)—from the UK Biobank, alongside data on Suicide and intentional self-harm (n = 342,499) from the FinnGen Biobank. Additionally, we utilized genome-wide association summary statistics data on seven subcortical brain volume and Intracranial Volume from the ENIGMA2 study.
Linkage Disequilibrium score regression was deployed to ascertain the genetic relationship between suicidality and subcortical brain volume, while Genomic Structural Equation Modelling (GenomicSEM) analyses were deployed to identify common genetic factor patterns. Our results revealed a nominal genetic correlation between Suicide from FinnGen and Intracranial Volume Furthermore, a common genetic factor was identified, comprising two categories: one including Suicide Attempt, Ever Self-Harmed, and Thoughts of Life Not Worth Living from the UK Biobank; and the other encompassing Suicide from FinnGen, Intracranial Volume, and subcortical brain volumes. This pattern led to a variant-based GWAS meta-analysis (RE2C and METASOFT) as well as gene/subnetwork meta-analysis (ancMETA) to uncover potential significant variants and genes per group of traits. In the first category, our variant-based GWAS meta-analysis uncovers 37 significant variants with the top three significant located within the *DCC* gene (rs17408393, rs62099230, rs17487277). The gene/subnetwork GWAS meta-analysis reveals 893 significant genes whereby 50 were detected as hub genes. The top significant hub genes include the top significant genes were *GPHN* (p-value = 0.00022), *RGS2* (p-value = 0.004), and *ATP1A1* (p-value = 0.0045).
In the second category, the variant-level GWAS meta-analysis identified 484 significant variants with rs6567261 (5.68×10^{-30}), rs11754988 (5.17×10^{-27}), and rs56161836 (6.69×10^{-27}) identified as top significant. The gene/subnetwork GWAS meta-analysis reveals 402 significant

genes with 22 significant hub genes. The most significant hub genes included *NEB* (p-value = 0.012), *EEF1D* (p-value = 0.013), and *B2M* (p-value = 0.019).
Network, pathway, and Gene Ontology analyses of these joint datasets uncovered enriched pathways and biological processes linked to blood-brain barrier permeability and inflammation. Our findings suggest a biological continuity in suicidality, marked by an inflammatory signature present in both blood and brain tissues, implying a common heritability. These insights underscore the role of brain and peripheral blood inflammation in suicide risk, offering promising avenues for targeted interventions and personalized treatments to reduce suicidality in vulnerable populations.

5.1. Introduction

Suicidality has become an increasingly critical issue within public health, claiming approximately 700,000 lives globally each year and maintaining a suicide rate of 9.0 per 100,000 individuals worldwide [1]. In the United States, it was the 12th leading cause of death from 2010 to 2018 [2]. The economic impact of suicidal behaviour is profound, with an estimated cost of $70 billion annually in the U.S. alone (CDC, 2020). Research has highlighted the genetic basis of suicidality, complementing the roles of environmental and individual factors [3,4]. For instance, monozygotic twins demonstrate a significantly higher likelihood of suicide attempts and completions compared to dizygotic twins [4]. Genome-wide association Studies (GWAS) have identified a Single Nucleotide Polymorphism (SNP) heritability of 3.5% in the UK Biobank and 6.8% in the International Suicide Genetics Consortium meta-analysis [5,6].
Neuroimaging studies have indicated associations between changes in subcortical structures and suicidality risk [7,8,9]. These findings align with the brain-centric diathesis-stress model of suicidal behavior [10], suggesting brain changes contribute to suicide risk. However, conflicting reports exist, with some studies finding no significant association between suicidality and subcortical brain volume [11]. For instance, the ENIGMA-MDD consortium found no significant differences in subcortical regions among individuals with or without suicidal ideation or behaviour. Another study involving adolescents with major depressive disorder did not find a link between suicide attempts and subcortical alterations [12]. Such discrepancies may stem from sample heterogeneity and the acute nature of suicidal behaviour. Similarly, brain volume has been shown to possess a heritable component [13]. Twin studies have revealed genetic influences on both overall brain and subcortical volumes [14,15]. Notably, GWAS have identified five genetic variants associated with the sizes of the putamen and caudate nucleus among seven subcortical brain regions [16]. More recent GWAS have discovered numerous genetic variants linked to brain morphometry [17]. Despite these insights, the extent of shared genetic loci between suicidality and subcortical brain volume remains underexplored, and the common underlying features are not fully understood. Moreover, the genetic overlaps at the polygenic level are still inadequately comprehended. Genetic investigations may provide a clearer understanding of the overlapping psychopathology between suicidality and brain volume than imaging studies alone.
Recent research has proposed the existence of a genetic 'p factor', indicating shared genetic variance across various disorders, particularly psychiatric symptoms [18,19]. This conceptualization suggests shared components in the underlying pathophysiology of mental disorders, potentially explaining their comorbidity. Utilizing large-scale GWAS datasets on suicidality and subcortical brain volume, this study aims to elucidate the shared genetic architecture between these phenotypes. We introduce a common factor model extending the

genomic 'p factor' to include suicidality and subcortical brain volume through Genomic Structural Equation Modelling (Genomic SEM). We conducted variant-based and gene/pathway-specific GWAS meta-analyses to identify loci significantly associated with this common factor. Furthermore, we sought to uncover cross-disorder risk loci between subcortical brain volume and suicidality using our common factor-informed approach, aiming to elucidate shared molecular mechanisms.

5.2. MATERIALS AND METHODS

We acquired Genome-Wide Association Study (GWAS) summary statistics pertaining to Suicide or other intentional self-harm (SUIC) from the FinnGen Biobank (https://www.finngen.fi/en/access_results), as well as data on Thought Life Not Worth Living (TLNWL) and Ever Self-Harmed (ESH) from the United Kingdom Biobank/Neale lab, Attempted suicide (SA) from the study led by Erlangsen et al. (2020) which can be retrieved within the iPSYCH Biobank [20]. Additionally, summary-level data on seven subcortical brain volumes including Amygdala (AMY), Accumbens (ACC), Caudate (CAU), Hippocampus (HIP), Pallidum (PAL), Putamen (PUT), and Thalamus (THA) with the Intracranial Volume (ICV) were sourced from the ENIGMA2 study, accessible via the public database (http://enigma.ini.usc.edu/research/download-enigma-gwas-results/). All samples were of European ancestry, and comprehensive details regarding sample collection, genotyping, processing, quality control, and imputation procedures for each GWAS have been previously documented and briefly outlined [16,21]. Details regarding the number of samples are outlined in **Table 5.1**.

Table 5.1. Summary information of the phenotypes of our study

Phenotype	**#Case**	**#Controls**	**Sample size**	**Source**
SUIC	1,361	341,138	342,499	FinnGen
TLNWL	NA	NA	117,291	United Kingdom Biobank/Neale lab
ESH	5,099	112,634	117,733	United Kingdom Biobank/Neale lab
SA	6,024	44,240	50,264	iPSYCH
Accumbens	NA	NA	13,112	ENIGMA2
Amygdala	NA	NA	13,160	ENIGMA2
Caudate	NA	NA	13,171	ENIGMA2
Hippocampus	NA	NA	13,163	ENIGMA2
Pallidum	NA	NA	13,142	ENIGMA2
Putamen	NA	NA	13,145	ENIGMA2
Thalamus	NA	NA	13,193	ENIGMA2
ICV	NA	NA	11,373	ENIGMA2

Upon retrieving data from the FinnGen database, UK Biobank and ENIGMA, we initiated a meticulous process of data refinement. Initially, we conducted data cleaning to ensure its quality and reliability. Duplicate Single Nucleotide Polymorphisms (SNPs) were removed, and we extracted SNPs with a Minor Allele Frequency (MAF) exceeding 0.01. Additionally, SNPs with conflicting alleles and those with missing information within the Genome-Wide Association Study (GWAS) summary statistics for each disorder were excluded from further analysis.

5.2.1 SNP-Based Heritability and Genome-wide Genetic Correlation

To gauge the portion of phenotypic variance attributable to common genetic variants, known as SNP-based heritability (h^2 SNP), we employed univariate LD-score regression (LDSC) [22]. This method was implemented using the Genomic SEM R package [23]. We adhered to default LDSC settings for quality control processes, which involved filtering SNPs to HapMap3, excluding SNPs within the Major Histocompatibility Complex (MHC) region, and removing SNPs with a MAF less than 1%. The defaults in LDSC were followed in the quality control (QC) processes for creating the genetic covariance (S) and sampling covariance (V) matrices. The MHC region, characterized by a complex gene network, often contains SNPs with disproportionately large effect sizes, thus necessitating its exclusion to prevent skewing results from heritability and genetic correlation studies, as well as in the genomic SEM analyses [23]. LD scores used in the analysis were derived from the 1000 Genomes European sample, limited to HapMap3 SNPs for reliable heritability estimates.

5.2.2 Genomic Structural Equation Modelling Analysis

Genomic factor analysis was conducted using the Genomic SEM R package. Initially, a genomic exploratory factor analysis (EFA) was performed to determine the optimal number of factors describing shared genetic variation. This informed subsequent genomic confirmatory factor analysis (CFA) to estimate model parameters for fitting. We employed diagonally weighted least squares estimation due to its robustness when modelling traits with varying characteristics. Model fit was evaluated using established criteria for absolute fit, including the AIC (Akaike Information Criterion), a measure used to compare the quality of statistical models, with lower values indicating a better fit, the standardized root mean square residual (SRMR) with values ≤ 0.10 indicating moderate fit and SRMR ≤ 0.05 indicating good fit; comparative fit index (CFI) with values ≥ 0.90 indicating moderate fit and CFI ≥ 0.95 indicating good fit; and lower chi-square statistic with p-value less than 0.05 suggesting a precise match and greater fit [23]. We use this approach to derive a potential common factor model and thereafter perform GWAS meta-analyses at SNP, gene and sub-network levels encompassing the phenotypes detected within the potential common factor.

5.3. RESULTS

5.3.1 SNP-Based Heritability and Genome-Wide Genetic Correlations

The heritability estimates (see **Table 5.2**), expressed on the observed scale, were derived from our analysis. For traits exhibiting lower-than-usual heritability estimates with greater standard errors compared to other studies, the corresponding SNP-based heritability couldn't be identified due to insufficient statistical power. Utilizing bivariate LDSC (Bulik-Sullivan et al., 2015) implemented into the R package GenomicSEM [22] between the twelve disorders, we

estimated genetic correlations (rg). However, it's important to note that the unbiased estimates provided by LDSC may exceed the range (-1 to +1) under certain conditions, such as large standard errors or highly significant genetic correlations between studies. Our analysis could not generate the genetic correlation estimate between the Amygdala and the rest of the phenotype due to its negative heritability estimate.

Table 5.2. Heritability estimates from our Analysis

Trait	h2	h2(SE)	Z-score	Lambda GC	Mean Chi^2	h2_inter	h2_inter_se	#SNPs for heritability analysis
SUIC	0.0025	0.0013	2.02	1.0292	1.0232	1.0065	0.07	1150849
TLNWL	0.0735	0.0054	13.7	1.1577	1.1788	1.0086	0.0072	1078769
ESH	0.0217	0.0044	4.96	1.0535	1.0613	1.0107	0.0066	1078769
SA	0.08	0.0122	6.6	1.0987	1.1107	1.0221	0.0091	922234
Accumbens	0.0905	0.0379	2.39	0.9967	1.0027	0.9796	0.0062	1171081
Amygdala	-0.0197	0.0322	-0.613	0.9944	0.9964	1.0014	0.0059	1171167
Caudate	0.2495	0.00397	6.28	1.0273	1.0326	0.9691	0.0062	1171185
Hippocampus	0.1542	0.0386	4	1.0103	1.0244	0.9844	0.0067	1171208
Pallidum	0.1551	0.0415	3.74	1.0065	1.0199	0.9799	0.0068	1171081
Putamen	0.2972	0.0481	6.17	1.0141	1.0268	0.951	0.0075	1171189
Thalamus	0.1314	0.0379	3.46	1.0065	1.0151	0.9816	0.0065	1171264
ICV	0.1845	0.00436	4.24	1.0383	1.0417	1.0008	0.0066	1171991

Our study identified a marginal positive genetic correlation between SUIC and intracranial volume (ICV) (rg = 0.47; p-value = 0.024) and a negative genetic correlation (however not significant) between SUIC and accumbens (rg = -0.52; p-value = 0.93). (see **Figure 5.1**). There are notable positive genetic correlations between several subcortical brain volumes (e.g., accumbens, putamen, caudate, pallidum, thalamus). We found significant genetic correlations between the putamen (PUT) and accumbens (ACC) (rg = 0.51; p-value = 0.043), caudate (CAU) and accumbens (ACC) (rg = 0.56; p-value = 0.0168), thalamus (THA) and accumbens (ACC) (rg = 0.52; p-value = 0.022), and a strong positive genetic correlation between the pallidum (PAL) and thalamus (THA) (rg = 0.6; p-value = 0.02). Other Suicidality-Related Traits (ESH, SA, TLNWL) exhibit various correlations with each other and non-significant correlations with brain structures, with ESH and SA showing high significant correlations with each other (rg = 1.02; p-value = 2.45×10^{-14}). The pattern of correlations highlights potential shared genetic underpinnings between certain brain volumes and suicidality, warranting further investigation into the underlying mechanisms. This analysis provides insight into the genetic architecture connecting brain structures and suicidality-related traits, suggesting both shared and unique genetic factors across these phenotypes.

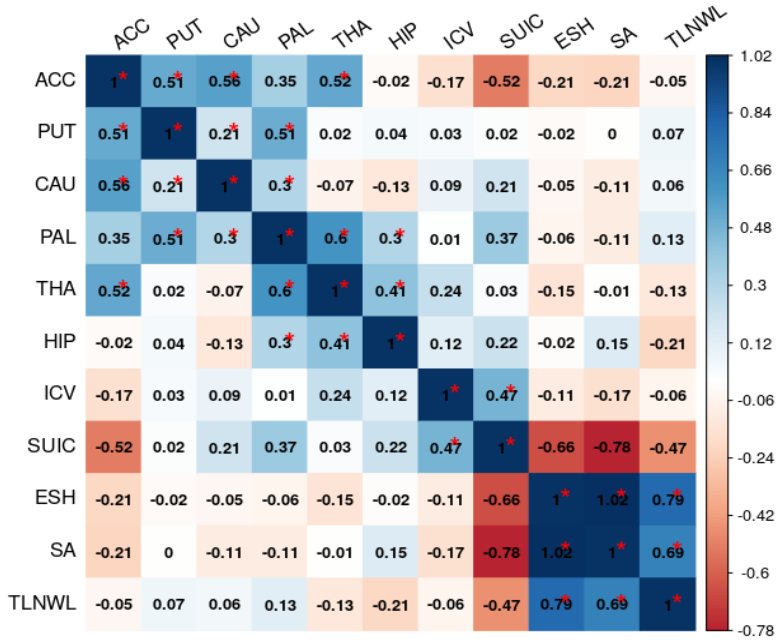

Figure 5.1. The heatmap shows the genetic correlations (rg) between various brain structures and suicidality-related traits. The values represent the strength and direction of the genetic correlations, with significant (P-values less than 0.05) correlations indicated by asterisks (*). The colour scale ranges from blue (positive correlations) to red (negative correlations), with darker shades representing stronger correlations.

5.3.2 Genomic Structural Equation Modelling Analysis

First, we ascertained the level of common genetic variance between all our included traits by testing the performance level of a common genetic factor. The common factor model converged with freely determined loadings, however, the fit was not fair enough(chisq(44) = 215.0768, $P_{chisq} = 2.21\times10^{-24}$, AIC = 259.0768, CFI = 0.696, SRMR = 0.194)(**Figure 5.2**).

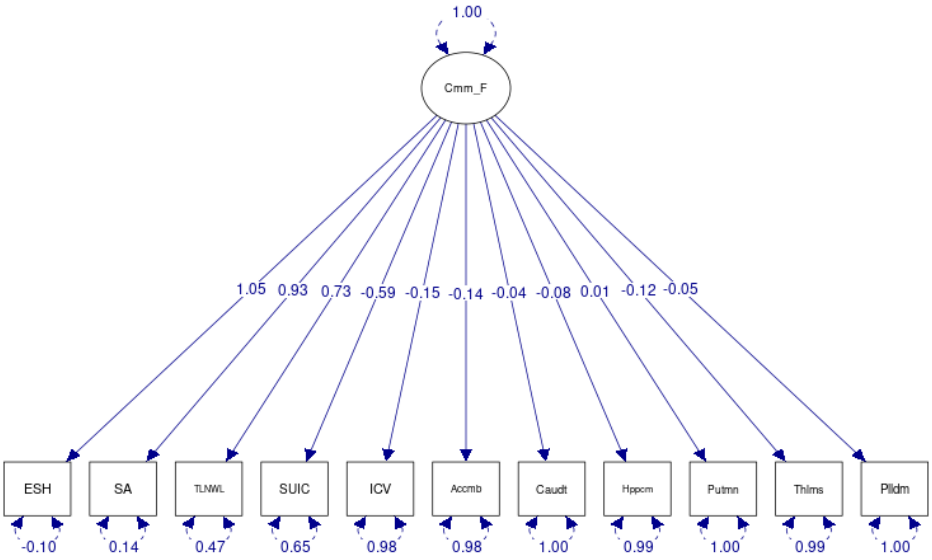

Figure 5.2. Path diagram for the single factor common factor model, which shows the overall common variance among all included traits. Ellipse indicate latent variables; rectangles indicate observed variables/traits. Numbers on arrows are standardized factor loadings and numbers at the end of arrows are residual variances.

Our genomic SEM analysis reveals an intriguing revised common factor model that fits the data well, with the best-fit statistics (chisq(15) = 25.69, P_{chisq} = 0.04, AIC = 127.69, CFI = 0.981, SRMR = 0.047) (Figure 3). This model identifies a common latent factor divided into two distinct groups of phenotypes. The first group includes the suicidal traits from the UK Biobank (ESH, SA, and TLNWL) highlighted in red, while the second group includes SUIC, ICV, Accumbens, Caudate, Hippocampus, Pallidum, Thalamus, and Putamen highlighted in green. This suggests that SUIC has a closer genomic link with subcortical brain volume and ICV compared to the suicidal traits ESH, SA, and TLNWL. However, both groups of traits exhibit the same genomic common factor, indicating the presence of a shared molecular mechanism.

5.3.3 GWAS Meta-Analysis at Variant and Gene Level

We conducted a variant-based GWAS meta-analysis using RE2C (v1.06) [24] to account for sample overlap among GWAS summary data. Significant variants were identified based on the RE2C P-value statistic (RE2C*P $< 5 \times 10^{-8}$). Variants that became significant after meta-analysis but did not reach genome-wide significance in individual trait GWAS datasets were considered novel [25]. In addition to the RE2C model, we performed cross-trait GWAS meta-analyses using both fixed effect (FE) and modified random effects (RE2) models [26], integrated into the METASOFT software (http://genetics.cs.ucla.edu/meta/). The FE model, which assumes the GWAS traits examined the same (fixed) effect, used the inverse variance weighted technique to estimate SNP meta-analysis statistics (effect size and p-value). In cases of heterogeneity, indicated by I^2 statistics, METASOFT employed the RE2 model to estimate SNP meta-analysis statistics. Gene and subnetwork-specific meta-analyses were conducted using ancMETA [27], which incorporates summary GWAS information and aggregates SNPs within nearby genes. ancMETA provides information on significant genes and hub genes based

on known biological protein-protein networks, shedding light on potential biological pathways shared across disorders. The meta-analysis GWAS focused on two sets of phenotypes:

Group 1: ESH, SA, and TLNWL.
Group 2: SUIC, ICV, Accumbens, Thalamus, Putamen, Caudate, Pallidum, and Hippocampus.

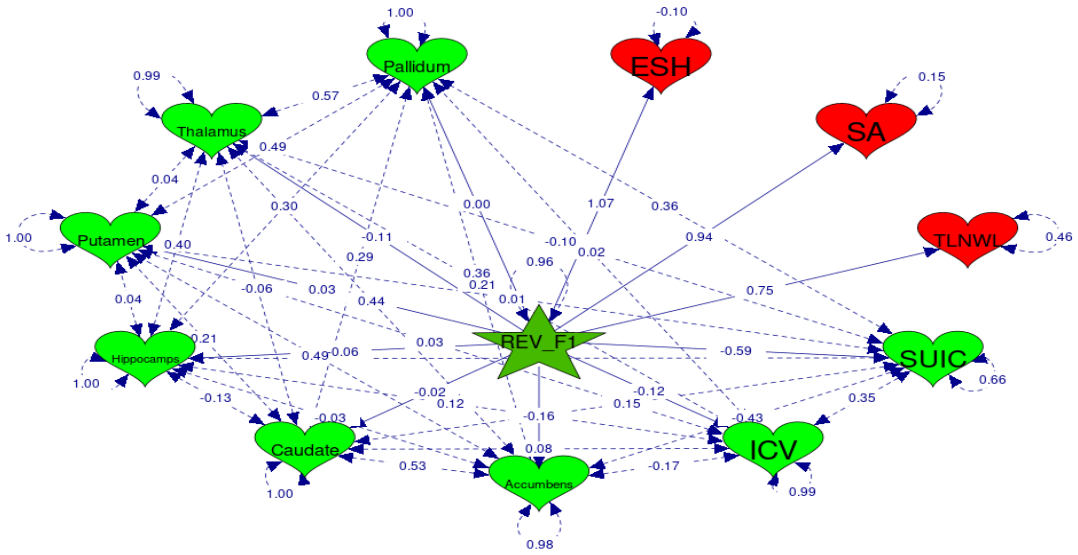

Figure 5.3. Path Diagram of the Revised Common Factor (Labelled "REV_F1"). This diagram illustrates the overall common variance among all included traits, representing observed variables with "heart" shapes and the unobserved (latent) variable with a "star" shape. It suggests two groups of disorders sharing the same common factor: the first group in red and the second group in green. One-headed arrows represent regression connections between variables, while two-headed arrows indicate the variance of a variable or the covariance between a variable and itself. This analysis aimed to identify overlapping genetic factors and elucidate potential shared molecular mechanisms across the included traits.

5.3.3.1 GWAS Meta-analysis at SNP level between ESH, SA and TLNWL

Our cross-trait meta-analysis using RE2C identified 37 significant variants (RE2C*$P < 5\times10^{-8}$) (**Table S15**) with overall small effects, in which 31 were found novel meaning not associated with any of the disorders ($P_{each_studies} > 5 \times 10^{-8}$).

Table 5.3 Top 5 Significant Loci from Cross-Trait Meta-Analysis of ESH, SA, and TLNWL (RE2C*P $< 5 \times 10^{-8}$)

Chr chromosome; bp base-pair position; ref reference allele; alt alternate allele; Beta effect size of the SNP; SE Standard error of the effect size; I^2 heterogeneity statistic quantifying the degree of heterogeneity.

Our results at SNP level exhibit that the top significant loci are located within the *DCC* gene and other loci were found in the *SH3GL3, STIM2, MEAF6* and *RSPO1* genes (**Table 5.3; Table S15**). The top four significant loci were found novel all located within the *DCC* gene; other new loci were found within *STIM2, MEAF6* and *RSPO1* genes (**Table S15**) adding value to the new genes found in previous literature [3].

5.3.3.2 GWAS Meta-analysis at SNP level between SUIC, ICV, Accumbens, Caudate, Hippocampus, Pallidum, Thalamus, and Putamen.

Our GWAS meta-analysis using the RE2C model identified 484 significant variants, all exhibiting low effect sizes (**Table 5.5**, **Table S16**). Among these, 64 SNPs showed potential pleiotropic effects, influencing multiple subcortical brain structures simultaneously, including the accumbens, caudate, hippocampus, pallidum, thalamus, and putamen. According to the SNP2GENE option from the FUMA analysis, the genes located near these significant loci exhibit enrichment across various brain regions. The highest levels of enrichment were found in the hypothalamus, brain cortex, and frontal cortex (**Figure 5.4A**). However, the genes near the pleiotropic loci showed enrichment in nearly all parts of the brain, except the putamen basal ganglia and the spinal cord (**Figure 5.4B**).

Figure 5.4. **A**- Bar plot showing enrichment tissues of all the nearby genes issues from significant cross-associated SNPs; **B**- Bar plot showing enrichment tissues of nearby genes from the significant potential pleiotropic (Accumbens, Caudate, Hippocampus, Pallidum, Thalamus, and Putamen combined) SNPs. The red colour speaks for significance and the blue one speaks for non-significance.

These findings suggest widespread genetic influences across various brain regions, emphasizing the importance of considering multiple brain structures when studying genetic associations with suicidality and subcortical brain volumes.

5.3.3.3 GWAS Meta-analysis at gene and sub-network level between ESH, SA and TLNWL

Gene-Level Analysis. At the gene level, ancMETA identified 893 significant genes (**Table 5.5; Table S17**) associated with ESH, SA, and TLNWL (overall P < 0.05). The top significant genes include *RANBP17* (p-value = 3.25×10^{-05}), *C6orf89* (p-value = 1.8×10^{-04}), and *GPHN* (p-value = 2.1×10^{-04}). *RANBP17* is Located on chromosome 5q35.1 and encodes RAN-binding protein 17, a nuclear transport receptor. It has been associated with the severity of suicide attempts in mood disorders at the polymorphism level [28]. *C6orf89* which encodes the bombesin receptor-activated protein (BRAP), is associated with allergic rhinitis and asthma and is potentially implicated in the stress response of lung epithelia [31,32]. Studies in mice suggest that BRAP regulates dendritic spine development and synaptic plasticity in the hippocampus, providing a protective behavioral response to stress [29]. Regarding *Gephyrin* (*GPHN),* previous studies have linked exonic microdeletions in this gene to neurodevelopmental issues such as idiopathic generalized epilepsy [30], schizophrenia, autism spectrum disorder, and epileptic seizures. These findings suggest that while the effects of variants within these genes differ between studies, the aggregation of variant effects within these genes significantly contributes to the cross-phenotype association of ESH, SA, and TLNWL.

Sub-Network Level Analysis. At the sub-network level, ancMETA identified 50 significant hub genes (**Table S18**). Among these, the top significant genes were *GPHN* (p-value = 0.00022), *RGS2* (p-value = 0.004), and *ATP1A1* (p-value = 0.0045). These hub genes indicate that the aggregation's effect of variants within these genes significantly contributes to the cross-phenotype association at the pathway/gene set level, encompassing the phenotypes of ESH, SA, and TLNWL. Our FUMA analysis revealed that the significant genes and hub genes identified in our ancMETA results showed significant expression enrichment across all brain

regions. The top enriched tissues include the brain anterior cingulate cortex, cultured fibroblast cells, brain hippocampus, brain putamen basal ganglia, and brain substantia nigra (**Figure 5.5B).**

Previous studies highlighted the association between numerous variants within the *RGS2* gene and a higher risk of committing suicide [33, 34]. *ATP1A1* is among the members of the sodium/potassium pump (Na+/K+-ATPase) family that is expressed in the brain and is responsible for regulating the amounts of potassium and sodium across cellular membranes [35]. Previous research has verified the involvement of brain Na+/K+-ATPase α subunit isoforms in several behavioral features, particularly the α2 and α3 subunits that have been linked to mental and behavioral disorders in humans [36, 37]. Another study has shown the connection between ATP1A1 expression levels and clinical anxiety scores in major depressive disorder patients [38].

5.3.3.3.4 GWAS Meta-analysis at gene and sub-network level between SUIC, ICV, accumbens, caudate, hippocampus, pallidum, thalamus, and putamen.

Gene-Level Analysis. In a comprehensive GWAS meta-analysis, ancMETA identified 402 significant genes cross-associated with SUIC, ICV, and various subcortical brain regions, including the accumbens, caudate, hippocampus, pallidum, thalamus, and putamen (overall P < 0.05; **Table 5.6, Table S19**). The top significant genes were *RPL11* (p-value = 1.8×10^{-4}), *DDX4* (p-value = 4.03×10^{-4}), and *WDR55* (p-value = 1.06×10^{-3}). *RPL11* has been previously implicated in the ribosomal pathway, playing a role in the pathogenesis of mild cognitive impairment and Alzheimer disease [39]. It is also associated with brain arteriovenous malformations [40] and has been proposed as a biomarker for major depressive disorder [41] and low risk neuroblastoma [42]. *WDR55* encodes WD repeat-containing protein 55, which modulates ribosomal RNA biogenesis, cell cycle progression, and organ development. It has been identified as a significant CpG site and methylated region associated with depression risk in Chinese monozygotic twins [43].

Table 5.6. Top 3 significant genes and subnetwork hub genes from cross-trait meta-analysis between SUIC, ICV, accumbens, caudate, hippocampus, pallidum, thalamus, and putamen.

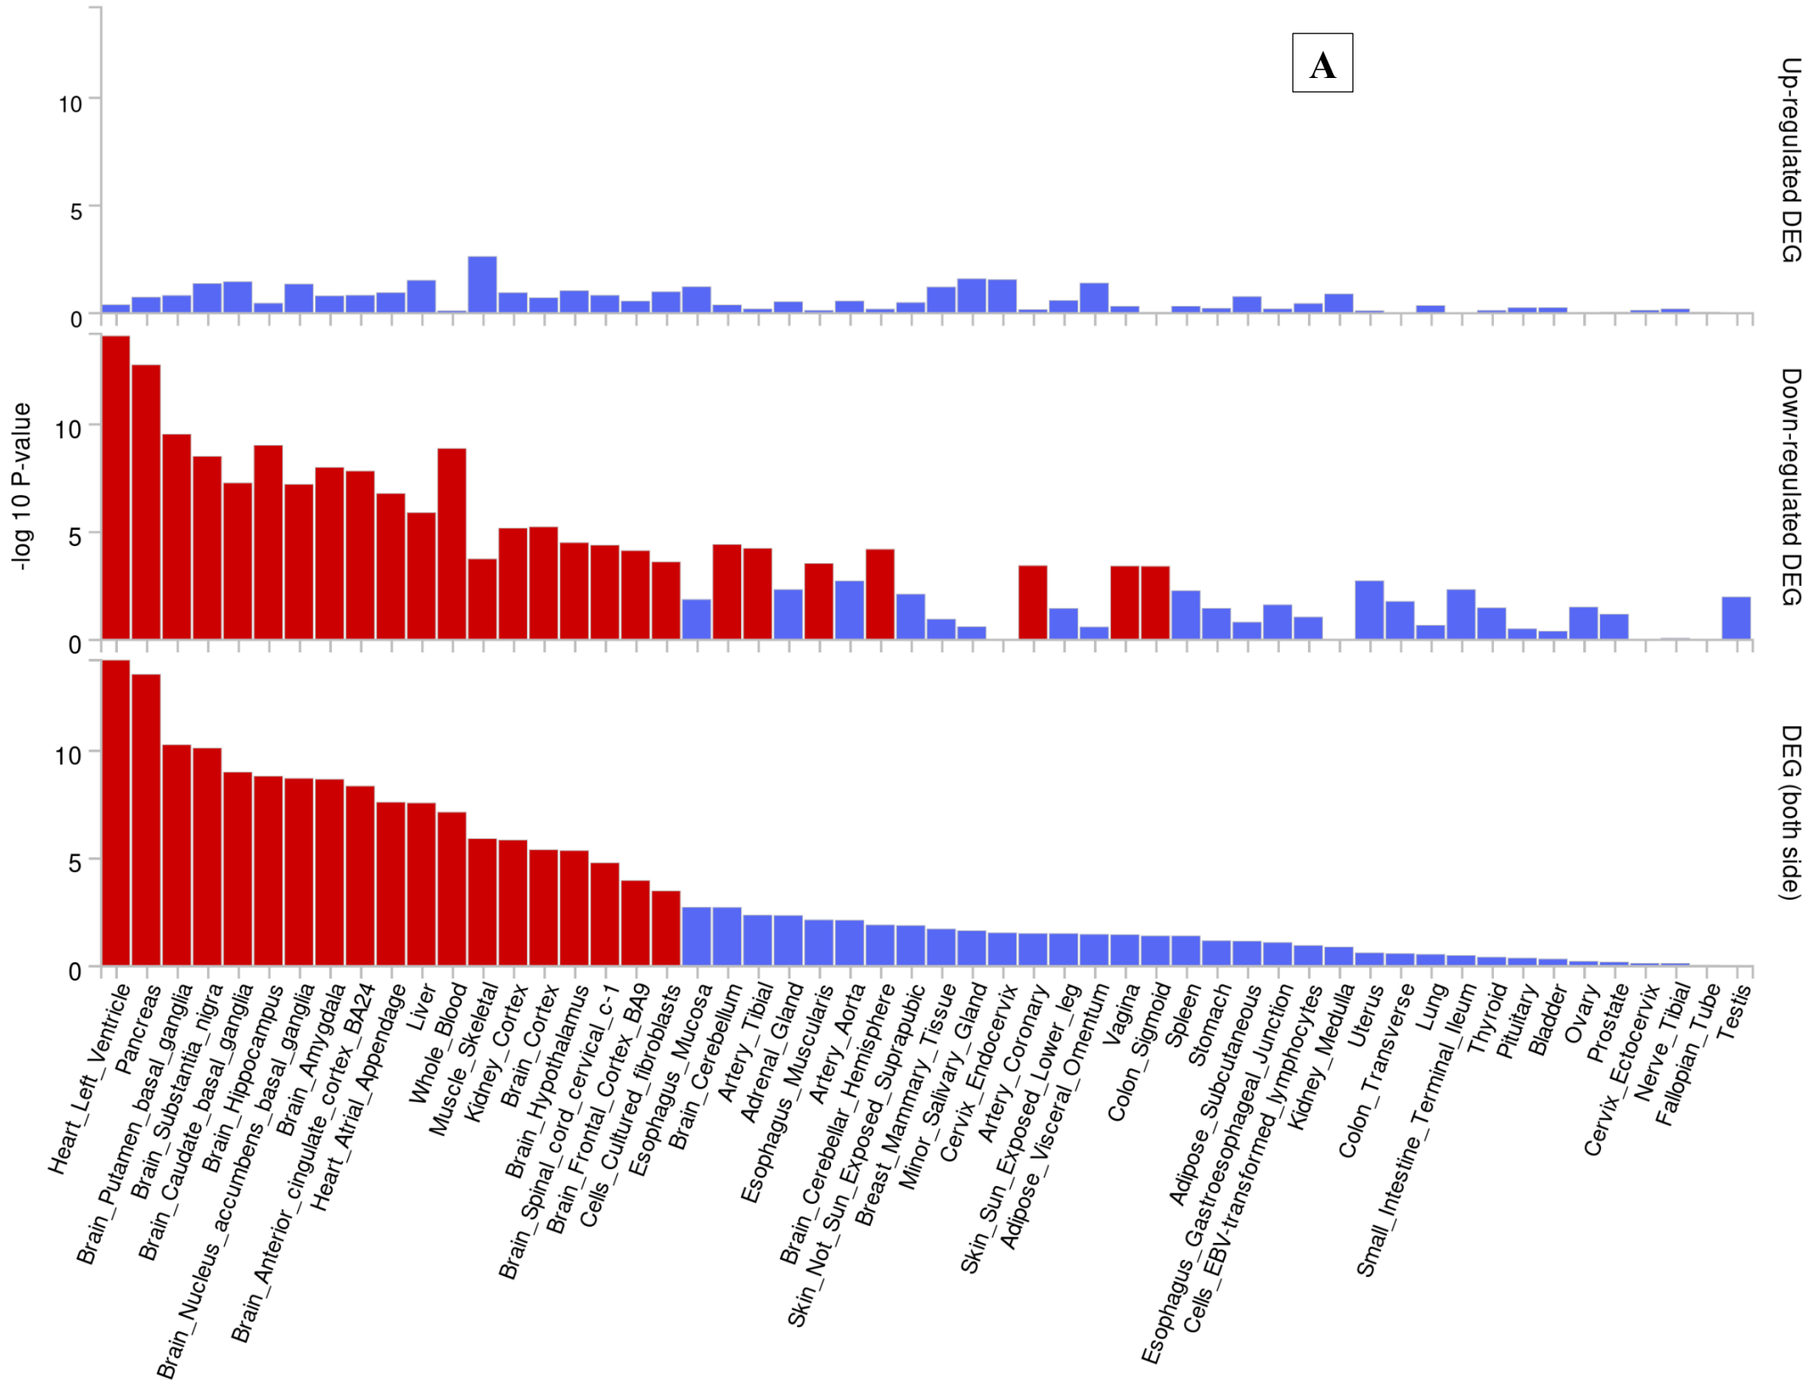
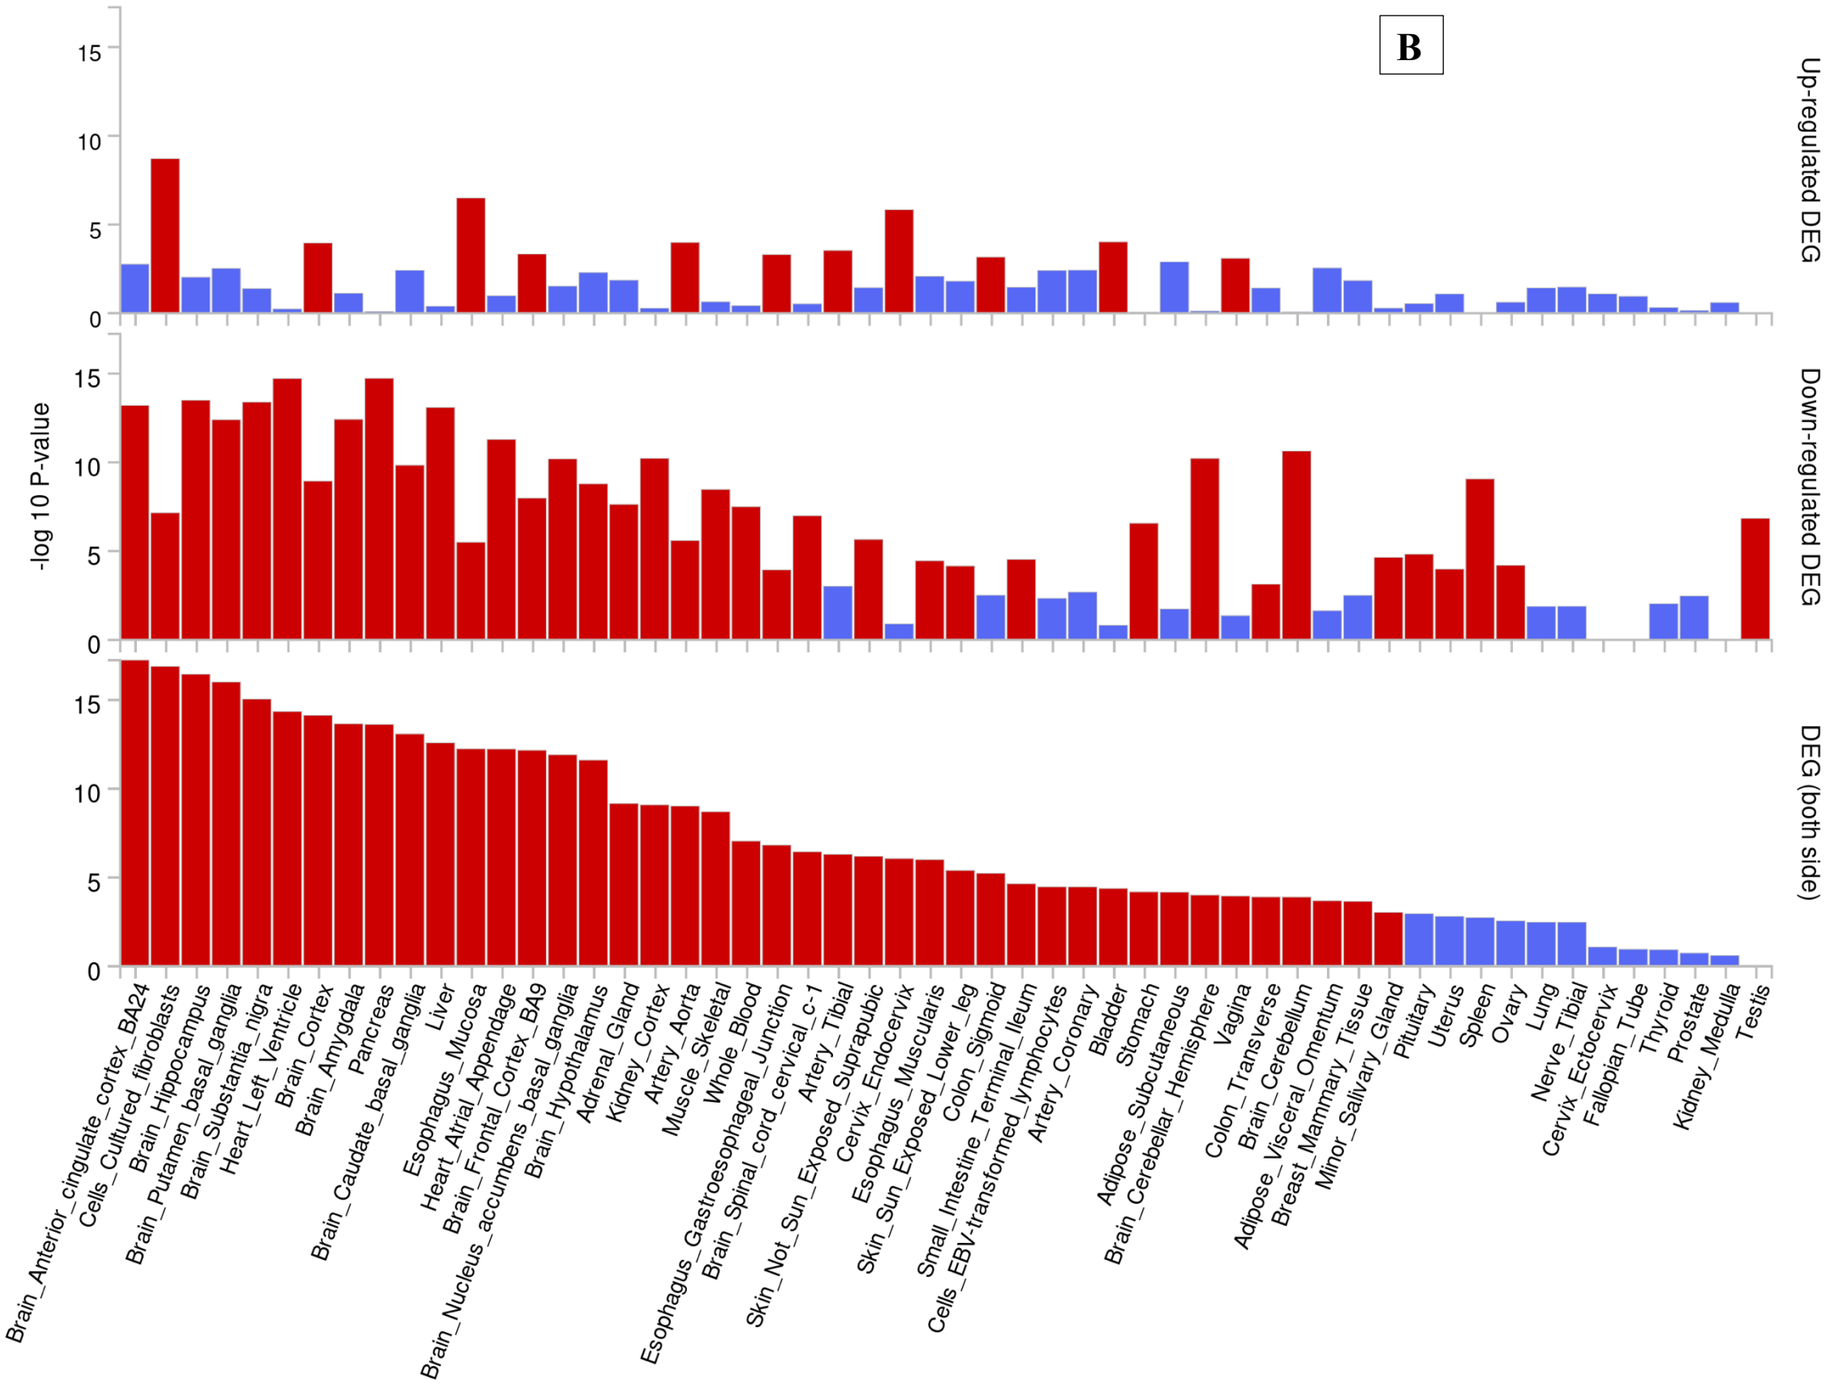
Q heterogeneity statistic indicating the presence or absence of heterogeneity; P_Q P-value of the Q estimate.

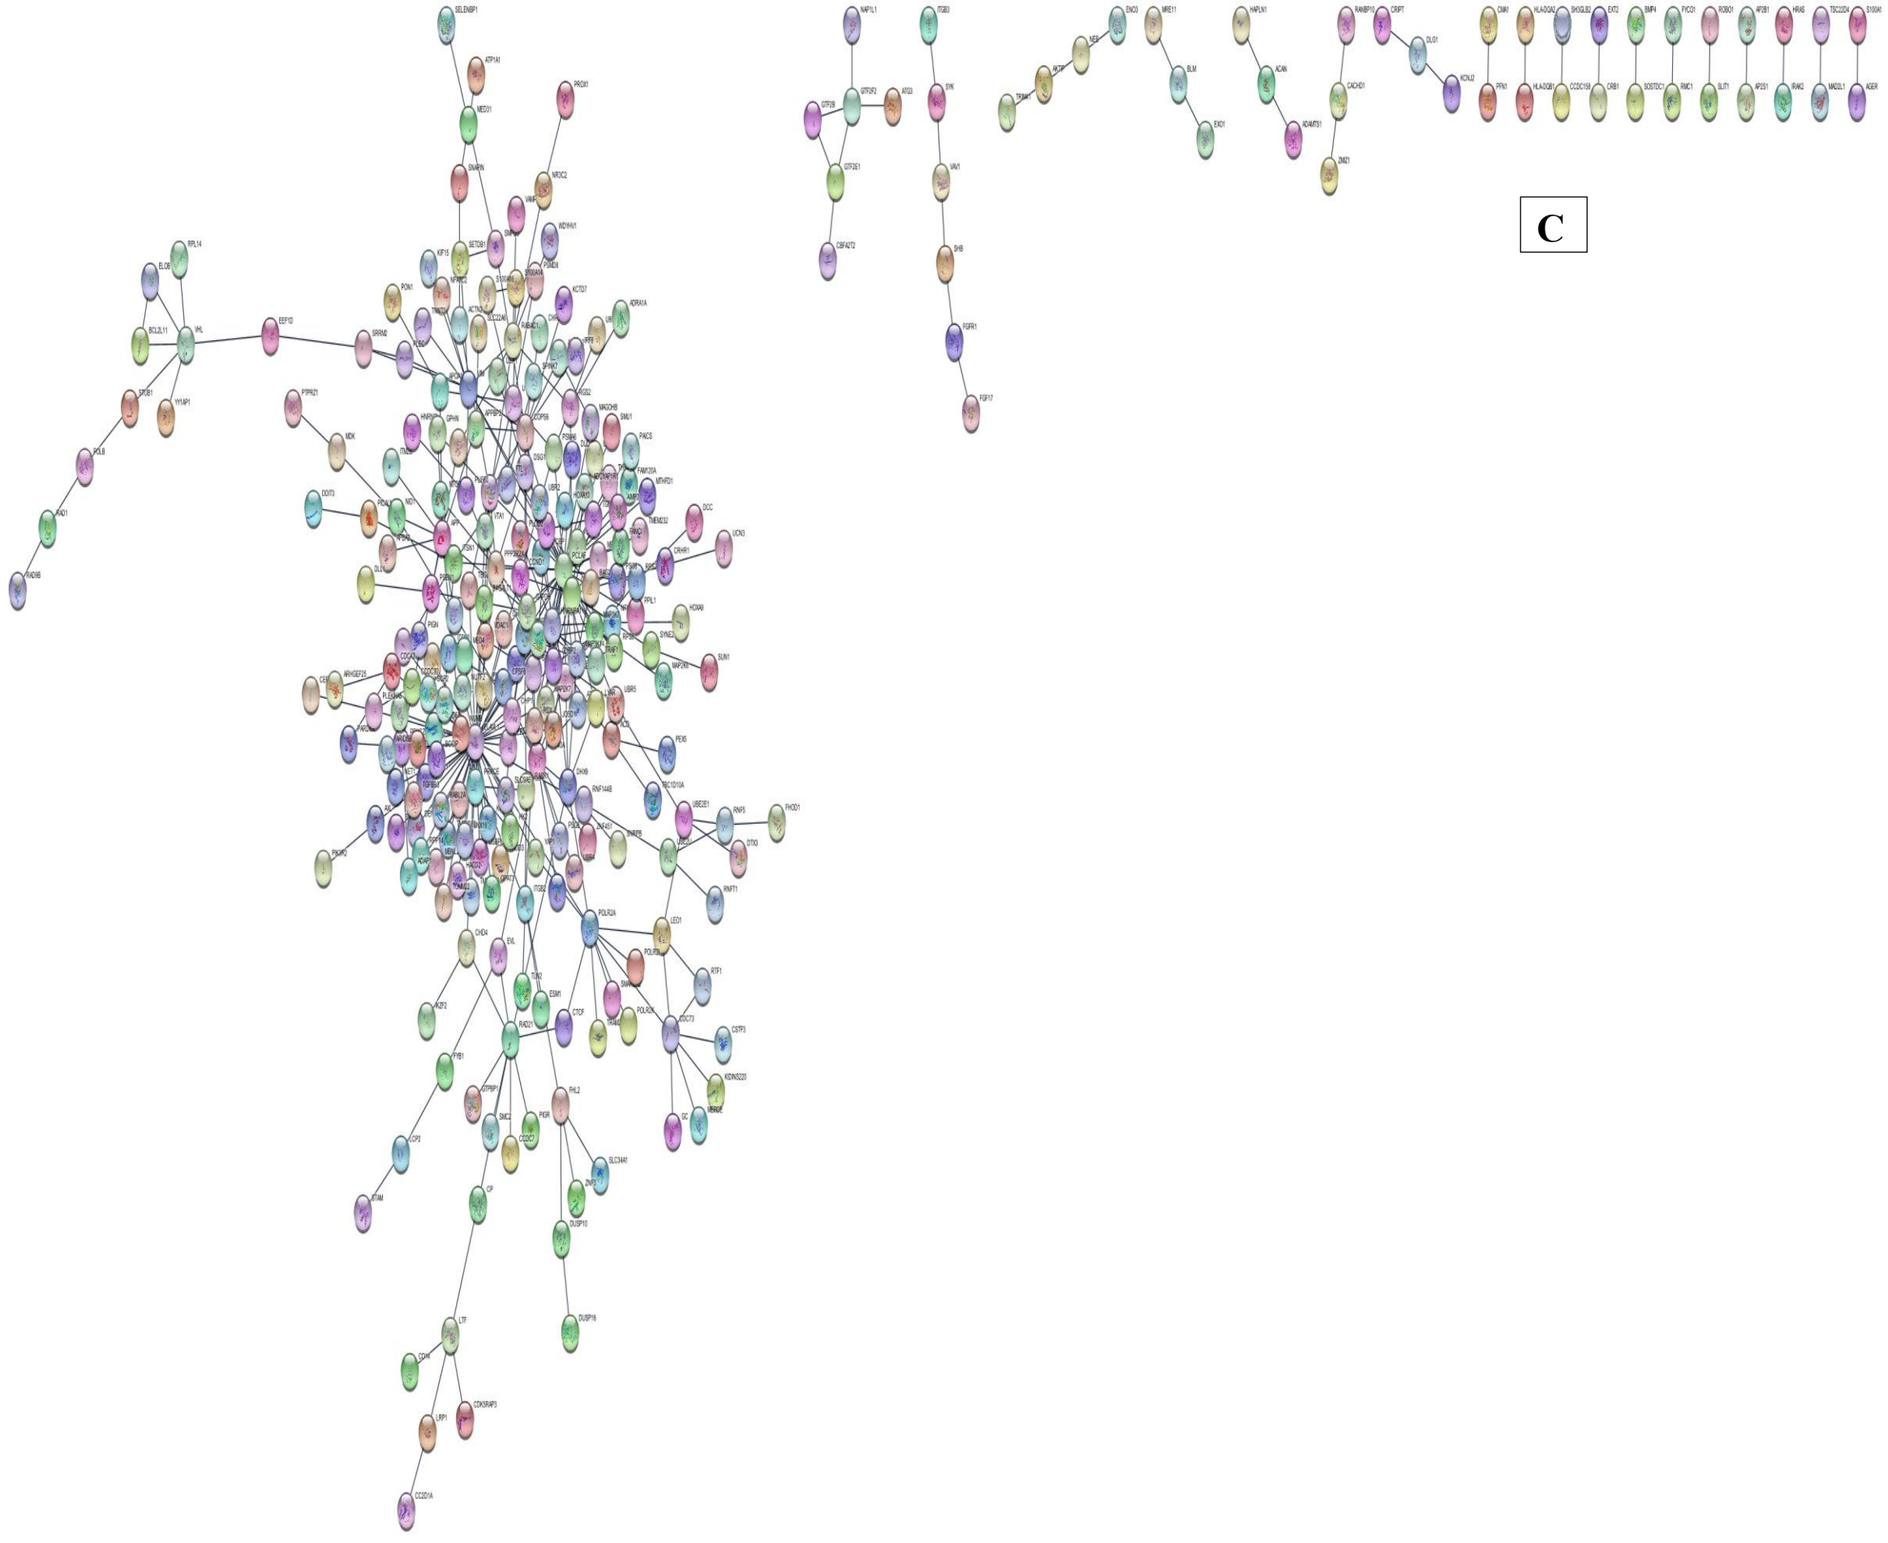
Sub-Network Level Analysis. At the sub-network level, ancMETA identified 22 significant hub genes (**Table S20**). Among the significant hub genes, *NEB* (p-value = 0.012), *EEF1D* (p-value = 0.013), and *B2M* (p-value = 0.019) were the most significant. Those significant hub genes suggest that although the variant effect within these genes varies, the aggregation/contribution of the effect of these variants within these hub genes converge significantly to the cross-phenotype association risk at pathway/gene set level encompassing the disorders SUIC, and brain structures: ICV, accumbens, caudate, hippocampus, pallidum, thalamus, and putamen. From our FUMA analysis, the significant gene and hub genes list from our ancMETA results showed significant enrichment of expression in all brain regions, except for the cerebellum and the cerebellar hemisphere which were specific for down-regulated expressed genes. The top enriched tissue includes the heart and left ventricle, the pancreas, the putamen,_basal ganglia, the substantia nigra, and the hippocampus(**Figure 5A**).



NEB (on chromosome 2q23.3) encodes nebulin, a protein extensively expressed in skeletal muscle, known for regulating muscle contraction and stabilizing thin filaments [44]. Immunohistochemistry has shown nebulin expression predominantly in the cytoplasm of pyramidal neurons and subcortical endothelial cells in the adult brain [45]. Whole exome sequencing identified two likely pathogenic *NEB* variants in a patient with cognitive impairment and dysmorphic features [46], suggesting a potential role for nebulin in the central nervous system and suicidality risk.



EEF1D (located on chromosome 8q24.3) undergoes alternative splicing in the brain and testis, affecting its expression. Mutations in EEF1D have been linked to neurodevelopmental disorders, microcephaly, and severe intellectual disability [47,48]. *B2M* (Beta-2-Microglobulin) has been identified as a biomarker for stress-related disorders, including suicide [49]. Additionally, *B2M* is associated with various neuropsychiatric phenotypes, such as alcoholism, autism, depression, eating disorders, pain, and aging, potentially mediating the effects of stress in these conditions [49].



5.3.4 Utilizing Network and Pathway Analysis Across Two Sets of Traits

In this study, we performed a network and pathway analysis involving two distinct sets of disorders. Initially, we used ancMETA to generate subnetworks containing significant genes and hub genes for each set of disorders. These subnetworks were then merged using Cytoscape version 3.7.2 (see **Figure 5C**). We conducted pathway enrichment analysis based on Gene Ontology (GO), Reactome pathways, and the Protein-Protein Interaction (PPI) network and

visualized the results with the StringApp plugin in Cytoscape version 3.7.2 [50;51]. The merged subnetwork of genes was assessed for enrichment in pathways and gene ontology using the Cytoscape plugin StringApp.

Figure 5.5 A: The bar plot shows tissue enrichment for all significant genes and hub genes identified through ancMETA analysis at the gene and subnetwork levels, using suicidality data from FinnGen and subcortical brain volume data from ENIGMA.
B: The bar plot displays tissue enrichment for significant genes and hub genes identified through ancMETA analysis at the gene and subnetwork levels, using emotional stability (ESH), social anxiety (SA), and tolerance to noise and workload (TLNWL) data from the UK Biobank. Red indicates significance, while blue indicates non-significance.
C: This potential subnetwork includes all significant genes and hub genes combined, generated by ancMETA from the two sets of phenotypes.

We identified significant (FDR < 0.05) 132 Reactome pathways, 50 KEGG pathways, and 51 WikiPathways in the resulting network. Notably, Rap1 signaling pathway (FDR value = 1.3×10^{-04}), Osteoclast differentiation (FDR value = 1.3×10^{-04}), T cell receptor signaling pathway (FDR value = 1.3×10^{-04}), and Viral carcinogenesis (FDR value = 3.9×10^{-04}) emerged as top significant pathways according to KEGG. Similarly, Disease (FDR value = 1.12×10^{-10}), Signaling By Receptor Tyrosine Kinases (FDR value = 3.9×10^{-09}), Signal Transduction (FDR value = 2.95×10^{-07}), Adaptive Immune System (FDR value = 1.5×10^{-06}), Infectious disease (FDR value = 4.01×10^{-06}), and Immune System (FDR value = 1.1×10^{-05}) pathways were identified as highly significant according to Reactome. Additionally, VEGFA-VEGFR2 signaling (FDR value = 6.4×10^{-08}), RANKL/RANK signaling pathway (FDR value = 7.97×10^{-07}), and T-cell receptor signaling pathway (FDR value = 5.07×10^{-05}) were prominent pathways according to WikiPathways. A comprehensive table listing each significant pathway per database and all significant GO biological processes, components, and functions can be found in **Tables S21-S27**. Furthermore, we compiled a list of pathogenic loci derived from our gene/sub-network GWAS meta-analysis using ancMETA on the two sets of disorders. The pathogenic criteria were based on the probability of being loss-of-function Intolerant > 0.9 [52].

Table 5.7. List of Pathogenic loci derived from our gene/sub-network GWAS meta-analysis using ancMETA on the two sets of disorders. The pathogenic criteria were based on the probability of being loss-of-function Intolerant > 0.9 [52].

5.4. DISCUSSION

The findings of this study offer crucial insights into the intricate genetic relationship between suicidality and alterations in brain structure, particularly in subcortical brain regions. This highlights possible shared molecular mechanisms and genetic underpinnings. The discovery of a common genetic factor between suicidality and subcortical brain regions underscores the existence of shared pathways and biological processes. Although we identified a nominal positive genetic correlation between SUIC and ICV, this emphasizes the complexity of the relationship and the need for further exploration using diverse methodologies and larger sample sizes [53,54]. Furthermore, our study demonstrated a common factor emerging from two cohorts: the suicide cohort from the UK Biobank (emotional stability, social anxiety, and tolerance to noise and workload) and the phenotypes, including SUIC from FinnGen and subcortical brain volume data. This suggests a direct overlap between SUIC and subcortical brain regions in the FinnGen cohort, compared to the UK Biobank cohort.

At the SNP level, our comprehensive analysis revealed significant variants within key genes, including *DCC*, *SH3GL3* (rs150002680), *STIM2* (rs28592695), *MEAF6* (rs6682470), and *RSPO1* (rs115632986) from the UK Biobank. This adds to the loci previously reported by Strawbridge and colleagues (2019). The SNP-based GWAS meta-analysis between SUIC and subcortical brain volume identified 484 significant variants with low effects, with 64 SNPs

showing potential pleiotropic effects on the accumbens, caudate nucleus, hippocampus, pallidum, thalamus, and putamen. These findings highlight the interconnectedness of genetic factors and support previous research linking suicidality to frontal-subcortical circuits [55,56]. Beyond individual variants, our gene and subnetwork GWAS meta-analysis unveiled numerous significant genes and hub genes implicated in both SUIC and altered brain volume. Particularly noteworthy are the loss-of-function-related genes, which indicate a pathogenic potential and heightened risk for suicidality (refer to **Table 5.6**).

The integration of these genetic findings into a comprehensive network analysis revealed enriched functionalities across various biological processes and pathways. Notably, genes related to neuroinflammation were significantly enriched, with pathways involving immune signalling, apoptosis, nervous system, neurodevelopmental disorders (such as Alzheimer and Huntington Disease), infectious diseases, and neurotrophic factors. These findings suggest potential targets for therapeutic intervention. Several pathways and GO enrichment strategies identified in our study align with previous findings that link the blood-brain barrier and suicidal risk [10,57,58,59].

Our findings indicate that the presence and severity of SUIC are associated with an inflammatory signature detectable in both blood and brain tissues. This suggests a biological continuity underlying SUIC, potentially indicating a common heritability. These results support the role of brain and peripheral blood inflammation in suicide risk, holding promise for targeted interventions and personalized treatment strategies to mitigate suicidality in vulnerable individuals.

The identification of genes involved in the dysregulation of the blood-brain barrier and immune function underscores the bidirectional communication between the brain and peripheral immune system in the context of suicidal risk. These results are corroborated by previous studies, further strengthening the validity of our findings and highlighting potential translational implications [60]. Our findings expand on previous research that identified genes substantially expressed in brain tissue and enriched in pathways related to immunologic markers, cellular stress response, gene regulation, and DNA repair [61,62,63].

The involvement of glial cells and microglia in inflammatory responses within the central nervous system [64] provides mechanistic insights into the pathophysiology of suicidality and altered brain volume. Glial cells, the most prevalent cells in the central nervous system, interact with immune system cells, neurons, and brain microvascular endothelial cells. Microglia, in particular, are resident innate immune cells. Studies have shown higher densities of activated microglia [65] in the white matter of suicide postmortem cases, as well as higher microglial priming and macrophage recruitment [66]. The transmission of inflammatory signals from the periphery to the brain via humoral transmigration or sensory afferent projections through the blood-brain barrier can stimulate microglial activation [67,68], and suicidality has been linked to anomalies in endothelial cells and the blood-brain barrier [69,70].

Despite these significant findings, several limitations warrant consideration. Generalizing our findings to other populations and ethnicities requires replication in diverse cohorts. Additionally, the reliance on GWAS summary statistics and the inherent statistical power of the original studies necessitates cautious interpretation of null results. Therefore, null conclusions in our research do not always imply a lack of association. The negative heritability of the amygdala did not provide a clear picture of genetic correlation and was not included in our SNPs, gene, and subnetwork GWAS meta-analysis. A well-powered GWAS of altered brain volume and suicidality could improve the detection of significant variants, genes, and pathways shared between these traits. Most of our suicide phenotypes have very low heritability, confirmed by the low effect sizes of relevant loci. Hence, the identified loci, networks, and functional pathways need validation in future studies with additional experiments, either *in* vivo or *in vitro*. Our findings are limited to autosomal chromosomal common variants; copy

number variants and other rare variants independently demonstrate strong penetrance for suicidal risk [71]. Known sex-specific effects in individuals with suicidal behavior [72,73] and brain development [74] further necessitate future studies on rare variants and sex-specific shared mechanisms.

In conclusion, this study represents a pioneering effort in elucidating the shared genetic architecture of suicidality and subcortical brain volumes. By uncovering overlapping genetic factors and biological pathways, we provide novel insights into the complex interplay between brain structure and suicidal behaviour. These findings hold promise for developing targeted interventions and personalized treatment strategies aimed at mitigating suicidality in vulnerable individuals. Further research exploring rare variants, sex-specific effects, and functional validations will be crucial for advancing our understanding of these complex phenomena and informing clinical practice.

Chapter SIX: CONCLUSION AND OUTLOOK

Meta-analysis has proven to be a powerful tool for integrating samples and results from different genome-wide association studies (GWASs). Significant discoveries have emerged over the past two decades; however, heterogeneity within and across populations has reduced the power of detecting true signals and hindered the replication of findings. Although incorporating multiple non-homogeneous populations in discoveries is promising, significant methodological challenges arise as the field moves towards merging studies from various disorders, populations, and study designs. Standard meta-analysis approaches are effective when combining GWASs to determine the average effect of a locus on a single trait. However, these methods are not ideal for analyzing multiple traits where the effect of individual susceptibility loci may manifest only in a subset of traits or in different directions for different traits. Additionally, understanding how multiple modestly associated variants within genes interact to influence a phenotype or multiple traits remains a challenge in uncovering the molecular mechanisms of disorders.

Cross-disorder and pleiotropy GWAS associations are increasingly recognized as significant in the genetic architecture of complex diseases. Approximately 17% of the genes in the NHGRI Catalogue of published GWAS have pleiotropic effects. However, current investigations into the pleiotropic mechanisms of complex disorders often rely on single pleiotropic genes, which can be functionally independent and sometimes provide insufficient information. Some pleiotropic genes are involved in various cellular activities, and the biological roles of many genes remain unknown. Consequently, identifying individual pleiotropic genes often yields limited insights into the genetic underpinnings of complex disorders.

In this dissertation, we reviewed current approaches for variant, gene, and pathway-based meta-analysis, discussing the benefits and pitfalls of each method. We proposed a Bayesian graph-based framework called "ancMETA," which performs gene- and sub-network/pathway-specific meta-analysis, accounting for variations in effect sizes across multiple independent GWAS studies. This technique accommodates the heterogeneity in effect sizes across various GWAS summary statistics from different cohorts. Through simulations and application to European Bipolar Disorder cohorts, our method identified effect sizes of genes and hub genes within subnetworks, aiding in understanding pathogenesis, disease risk prediction, and susceptibility to genetic diseases.

Beyond bipolar disorder, ancMETA was applied to identify significant genes and hub genes involved in shared mechanisms between suicide and various psychiatric phenotypes using GWAS summary statistics from the FinnGen database. GenomicSEM analyses revealed that several psychiatric disorders, including bipolar disorder, depression, disturbance of activity and attention, anxiety disorder, general anxiety disorder, alcohol use disorder, and post-traumatic stress disorder, share a genetic common factor with suicide, confirming comorbidity across psychiatric disorders. The significant hub genes and their associated subnetworks cross-associated with these phenotypes, helping to identify potential common molecular mechanisms contributing to the overlapping pathophysiology of these disorders. This analysis highlighted genetic loci that could be candidate drug targets and identified drugs that may be repurposed.

Furthermore, ancMETA was used to detect genes overlapping between suicidality and subcortical brain structures. The identified network of genes and pathway/enrichment findings suggest that the presence and severity of suicidality are associated with an inflammatory signature detectable in blood and brain, highlighting the role of brain and peripheral blood inflammation in suicide risk. The identification of genes involved in the dysregulation of the blood-brain barrier and immune function underscores the bidirectional communication between the brain and peripheral immune system in the context of suicidal risk.

Despite the promising results, this study has several limitations. The ancMETA analysis relies on GWAS summary statistics and protein-protein interaction (PPI) information from various databases, which may influence outcomes as PPI databases are updated. Additionally, studies with larger sample sizes from each GWAS would enable better investigation of epistatic interactions and provide greater resolution to current findings. Our ancMETA analysis and generated network of genes are based on candidate genes that may be updated over time and vary by population of interest. The findings of shared pathways are based on the identification of hub genes that may interact with other candidate genes. Furthermore, this framework does not account for sample overlap and phenotype correlation, which could be addressed in future research to capture candidate loci involved in disorder pathogenesis accurately. The method could be improved by assigning Bayesian priors that incorporate knowledge about the overlap (e.g. using genomic relationship matrix) by analytically computing the correlation between studies. Such statistics can be included in the pipeline of ancMETA at gene level and adjusting the effect size estimates accordingly. There is also a need to integrate summary-level data across multiple correlated phenotypes to uncover aggregate-level shared pleiotropic mechanisms. The lack of comprehensive knowledge of complex traits and the incomplete human protein interaction network poses challenges in directly comparing results from different pathway analysis methods. Furthermore, the application of ancMETA was done across studies with the same ancestry. There is a need to implement ancMETA in a cross-ancestry setting and assess its performance by comparing ancMETA with other tools with a similar methodology. Our findings reveal that the genes and pathways found via ancMETA corroborate with previous studies with no evidence of false positives. This suggests that ancMETA, in its current form can be applied in the context of sample overlap. However, though several adjustments need to be made to improve the efficacy of the tool, it will be necessary to assess the performance of ancMETA depending on the extent of sample overlap between studies.

The advent of advanced high-throughput technology has generated vast amounts of biological data. However, progress in understanding disease phenomena lags significantly behind data collection and integration. Many existing methods do not fully integrate information gathered on samples to improve estimate accuracy and unravel the underlying mechanisms of complex diseases. Traditional meta-analysis, which incorporates significance levels or effect sizes from similar datasets, has proven valuable in detecting significant biomarkers and replicating findings within single studies. This multi-study data integration, known as "horizontal genomic meta-analysis," has been widely applied in genomics [1,2,3] and transcriptomics [4,5]. Conversely, when different omics datasets from the same cohort of samples are joined, the datasets are vertically aligned, with samples matched on the columns. This approach, called "vertical genomic meta-analysis," [6, 7] is popular in systems biology and involves merging data from multiple levels of the 'omics-cascade,' such as transcriptional and metabolic data from the same patient cohorts [6].

As multi-level omics datasets, including SNPs, gene, protein, and metabolite expression data, are increasingly collected from large clinical cohort studies, the vertical integration of omics

data has become a prominent focus in bioinformatics. Integrating multi-omic data, including transcriptomics, genomics, proteomics, microRNA, and phenomics, is progressively revealing additional insights into disease pathogenesis. We propose extending the ancMETA tool to combine multi-omics data from different experiments on the same samples (vertical integration) and across studies on the same phenotype (horizontal integration). This will enhance understanding and accuracy of the genetic mechanisms underlying complex diseases. With the eased limits on data integration, this framework is expected to be widely applicable as large databases of varied data types become available. Further studies with larger sample sizes and multi-omics data integration can elucidate polygenic effects in complex traits, extending analysis to genome partitioning, risk prediction, and genetic correlations.

Concluding Summary

In conclusion, this dissertation underscores the efficacy and potential of meta-analysis in synthesizing data from diverse GWASs to uncover the genetic underpinnings of complex disorders. Despite the challenges posed by heterogeneity across populations and traits, our proposed ancMETA framework demonstrates significant advancements in addressing these issues by incorporating gene- and sub-network/pathway-specific analyses. The application of ancMETA to bipolar disorder and its shared mechanisms with other psychiatric disorders, as well as its extension to suicidality and subcortical brain structures, highlights its versatility and robustness in identifying significant genes and hub genes. These findings not only enhance our understanding of the genetic architecture of these complex traits but also pave the way for identifying potential drug targets and repurposing existing medications.

The limitations of this study, including the reliance on current PPI databases and the need for larger sample sizes, point to directions for future research. Integrating multi-omics data through both horizontal and vertical genomic meta-analysis presents a promising avenue for further elucidating the polygenic effects in complex traits. By extending ancMETA to incorporate a broader spectrum of omics data, we anticipate more precise and comprehensive insights into the genetic mechanisms underlying complex diseases.

Overall, this work contributes to the field of bioinformatics by offering a novel and robust framework for meta-analysis, addressing existing methodological hurdles, and providing a foundation for future research that integrates diverse and comprehensive datasets. Continued advancements in this area hold the promise of significantly improving our understanding of disease pathogenesis, risk prediction, and the development of targeted therapeutic interventions.

APPENDIX 1 (CHAPTER TWO)

1. Some Aggregation Techniques for SNP-based GWMA

1.1 P-value and Z-score Meta-analysis

P-value and Z-score of individual studies in a meta-analysis are simplistic and follow the usual statistical definition. Here is the p-value test statistic method introduced by Fisher [1], defined by

$$X_{2s}^2 = -2\sum_{i=1}^{s}\log(p_i) \sim \chi_{2s}^2 \quad (1)$$

where s is the number of studies and p_i is the individual p-value. The combined meta-analysis Z value can be computed with pi computed from two or more separate and independent studies, each with a corresponding Z-score Zi. This method is based on the average of the Z_i from each study and is derived using the sample size information, the p-values and direction of the effect, as mentioned below

$$Z = \frac{\sum_{i=1}^{s}\omega_i Z_i}{\sqrt{\sum_{i=1}^{s}\omega_i^2}} \sim N(0,1) \quad (2)$$

where $Z_i = \Phi^{-1}(1-\frac{p_i}{2})$ is the direction of effect; with ω_i the square root of the sample size and Φ, the standard normal cumulative distribution function. Although these methods are relatively straightforward to perform, the major limitation of this P-value meta-analysis is that there is no information regarding the effects of each study. Hence the overall estimate of the effect size cannot be determined, which results in a consistent loss of power and makes it difficult to quantitatively assess the magnitude of gene and SNP effects. Nonetheless, P-value and Z-score meta-analyses might be attractive approaches especially to conduct GWMA with low-frequency variants or rare variants wherein p-values or Z-test statistics are given with summary information rather than the effect size estimates [2].

1.2 Fixed Effect model (FEM)

Under the fixed-effect model (FEM), a summary effect across the component studies of a meta-analysis is estimated, which constitutes the main aim of the model. To compute the summary effect estimate, the model assumes that all studies in the meta-analysis have the same common effect and that the source of variability is only due to sampling noise. Each true-effect size from each study is assigned a weight which corresponds to the inverse of their observed variance; this implies that under this model, studies with larger sample sizes are assigned larger weights. More formally, for s studies in the meta-analysis, each having an estimated effect size y_i and standard error SE_i (for $i \in 1,...s$); assuming that $y_1 = y_2 = y_3 = ... = y_s$, the estimated overall effect size, β_{fix}, of a SNP is estimated using the inverse-variance weighted average method, as denoted by

$$\beta_{fix} = \frac{\sum_{i=1}^{s} \omega_i y_i}{\sum_{i=1}^{s} \omega_i} \quad (3)$$

with associated weights ω_i defined by

$$\omega_i = \frac{1}{SE_i^2} \quad (4)$$

and the estimated standard error labelled SE_{fix} of the overall effect, given by

$$SE_{fix} = \sqrt{\frac{1}{\sum_{i=1}^{s} \omega_i}} \quad (5)$$

The Z test statistic is defined by

$$Z_{fix} = \frac{\beta_{fix}}{SE_{fix}} = \frac{\sum_{i=1}^{s} \omega_i y_i}{\sqrt{\sum_{i=1}^{s} \omega_i}} \quad (6)$$

The test statistic follows a standard normal distribution under the null hypothesis of no association. The p-value of the association, assuming a two-sided test is given by $p_{fix} = 2\Phi(-|Z_{fix}|)$ where Φ is the cumulative density function of the standard normal distribution.

Fixed effect meta-analyses are easy to compute, and the results are relatively easy to interpret. This model is often used to combine evidence between discovery and replication cohorts in a GWAS to determine the "true" effect size of the marker on the phenotype. With the assumption that there is a single common effect underlying every study in the meta-analysis, the result of every study would be identical because there will be no between-study heterogeneity. This is useful if we aim to optimize power for detecting association. However, in the presence of heterogeneity, this association may not be possible to extend equally well to diverse admixed populations and the model underestimates the standard error of the combined effect estimates. Heterogeneity is an important aspect of meta-analysis studies since it elucidates the magnitude of the genetic effect across different populations and different biological settings and reveals the mechanism through which the variant acts on disease risk [3, 4]. GWMA could induce genetic heterogeneity of effect sizes which could be partly explained by the incorrect definition of the phenotype, concomitant phenotype, diverse study designs, studies carried out on diverse ancestral groups in different geographic areas, population stratification, the pattern of linkage disequilibrium, sex differences and gene-gene interactions and gene-environment interactions with differential non-genetic environmental exposures across different populations [2]. The FEM is the most popular approach in the synthesis of GWAS data but has limited power in the presence of genetic heterogeneity [2]. This limitation led to the development of the random-effect model, which attempts to account for and to model between-study heterogeneity in order to achieve higher power.

1.3 Random Effect model (REM)

The REM assumes that for $i \in 1,...s$, the true effect size for each study, $y_i \sim N(y, SE_i^2 + \tau^2)$, such that y denotes the average underlying summary effect and τ the heterogeneity (or between-study) variance. It is worth mentioning that estimates for the average random effect and extent of heterogeneity will expectedly be imprecise when meta-analyses comprise a few studies (i.e. ≤ 5 studies) [5]. Consequently, the new expression of the weight will be given by

$$\omega_i{}^* = \frac{1}{SE_i^2 + \tau^2} \tag{7}$$

The pooled effect estimator β_{ran} is similar to the fixed effect model in equation 3 except that the precision includes the between-study variance

$$\beta_{ran} = \frac{\sum_{i=1}^{s} \omega_i{}^* y_i}{\sum_{i=1}^{s} \omega_i{}^*} \tag{8}$$

and its estimated standard error labelled SE_{ran} is given by

$$SE_{ran} = \sqrt{\frac{1}{\sum_{i=1}^{s} \omega_i{}^*}} \tag{9}$$

and the test statistic is expressed as follows

$$Z_{ran} = \frac{\beta_{ran}}{SE_{ran}} = \frac{\sum_{i=1}^{s} \omega_i{}^* y_i}{\sqrt{\sum_{i=1}^{s} \omega_i{}^*}} \tag{10}$$

and its associated p-value is $p_{ran} = 2\Phi(1 - |Z_{ran}|)$ where Φ is the cumulative density function of the standard normal distribution. Once we estimate the random effect means and variance, we need to ascertain the homogeneity of the effect sizes, i.e., whether they are probably deriving from a single distribution of effect sizes. For this purpose, the homogeneity statistic Q, named Cochran's test statistic, is denoted by

$$Q = \sum_{i=1}^{s} \omega_i \left(y_i - \beta_{fix}\right)^2 = \sum_{i=1}^{s} \omega_i {y_i}^2 - \frac{\sum_{i=1}^{s} (\omega_i y_i)^2}{\sum_{i=1}^{s} \omega_i} \tag{11}$$

If the effect sizes are homogeneous, Q is distributed as a chi-square distribution with s-1 degrees of freedom [6, 7]. This statistic is widely used to assess heterogeneity; however, it becomes underpowered when the number of studies is small [7]. With the assumption of heterogeneity of the effect size for each SNP, the between-study variance of heterogeneity is expressed by

$$\tau^2 = \begin{cases} \dfrac{Q - s - 1}{\sum_{i=1}^{s} \omega_i - \dfrac{\sum_{i=1}^{s} \omega_i{}^2}{\sum_{i=1}^{s} \omega_i}} & if\ Q \geq s - 1 \\ 0 & if\ Q < s - 1 \end{cases} \tag{12}$$

Whereby Q is the Cochran test statistic as expressed in equation 11 and s is the number of studies. The value of τ^2 equal to zero indicates no variation between studies. Various other statistics have been proposed to overcome the underpower of Q. For instance, the I^2 index, given by $100 \times \frac{Q-(s-1)}{Q}$, measures the degree of true heterogeneity in a meta-analysis. This statistic does not depend on the number of studies and is interpreted as the percentage of total variation in study estimates that is due to heterogeneity, meaning between-studies variability [8, 6]. Higgins and colleagues consider values of I^2 less than 25% indicative of homogeneity, while values of I^2 between 25% and 50%, 50% and 75%, 75% and 100% show respectively small, moderate, and large degrees of heterogeneity [9].

Although REM and FEM have specific hypotheses, REM, under the null hypothesis of no association, relies on the assumption of between-study heterogeneity of the effect size, which do not unravel the occurrence of statistical heterogeneity as studies are combined in the same analysis structure. An alternative REM (representing a combination of both, hence REM-FEM) was proposed by Han and Eskin to address the issue of heterogeneous effect sizes and to achieve higher power compared to REM [10]. This model operates under the null hypothesis of common true effect size between studies, and variation of effect sizes across studies under alternative hypotheses. The details of the method are formalized below: The REM-FEM uses a likelihood ratio that takes each statistic as a single observation. Because there is no heterogeneity, the values of the true mean and the true variance are assumed to be nought under null hypothesis (true mean effect $\mu = 0$ and the heterogeneity variance $\tau^2 = 0$). The likelihood ratios L_0 and L_1, respectively, under the null and alternative hypotheses are given by

$$L_0 = \prod_i \frac{1}{\sqrt{2V_i}} \exp\left(-\frac{y_i^2}{2V_i}\right) \tag{13}$$

$$L_1 = \prod_i \frac{1}{\sqrt{2\pi(V_i + \tau^2)}} \exp\left(-\frac{(y_i^2 - \mu)^2}{2(V_i + \tau^2)}\right) \tag{14}$$

Where y_i and V_i represent respectively the effect size and the variance of the associated effect for study i. By testing whether $\mu \neq 0$ and $\tau \neq 0$, the maximum likelihood estimates of $\hat{\mu}$ and $\hat{\tau}$ are given using the approach of Hardy and Thompson [11]. Following these estimates, the likelihood ratio test statistic for this model is as follows

$$S_{RE-FE} = -2\log\left(\frac{SupL_0}{SupL_1}\right) = \sum_i \log\left(\frac{V_i}{V_i + \hat{\tau}^2}\right) + \sum_i \frac{y_i^2}{2V_i} - \sum_i \frac{(y_i - \hat{\mu})^2}{V_i + \hat{\tau}^2} \tag{15}$$

Under the assumption of equal sample size, the significance of the model is provided in a tabulated way with studies varying between 2 and 50. The model generates 10^{10} null statistics to construct the p-value table with a precision of up to 10^{-8}. For several sufficiently large studies, the statistic S_{RE-FE} follows, asymptotically, a mixture of chi-square distribution with 1 and 2 degrees of freedom [10].

Although the method can be extended to multiple diseases with similar etiology, one major challenge resides in the interpretation of the results. To address this issue, Han and Eskin introduced the Binary Effects Model [12], to be discussed in the next section.

1.4 Binary Effects Model (BEM)

In the classical random effect model, Han and Eskin (2012) discovered that the absence of the effect of a SNP is not evidenced by its non-significant p-value. In addition, they realized how complicated it is to plot the observed effect sizes and their confidence interval [12]. In light of these limitations, Han and Eskin proposed a new method for random effects meta-analysis for GWAS. This method, BEM, assumes two hypotheses. First, it accounts for the presence or the absence of an effect in a study, and second, in the presence of an effect, this effect is expected to be similar between the studies [13, 12]. The BEM uses a statistic called the m-value, which is the posterior probability that the effect exists in each study and proposes a weighted sum of Z-scores statistic which incorporates the m-values computed from the data as prior weights from each of the component studies [12]. More formally, let s be the number of studies and α_i be the observed effect size of study i (i = 1,...,s) with σ_i the associated variance.

Assuming no effect in study i, $P(\alpha_i|\text{no effect}) = f(\alpha_i,0,\sigma_i)$ whereby f is the probability density function of the normal distribution. In the case of effect in study i, $P(\alpha_i|\text{effect}) = f(\alpha_i,\mu,\sigma_i)$ whereby μ is the unknown effect size.

Here, they defined the z-score for each study i (Z_i) as the ratio between the observed effect size, α_i and its standard error, SE_i. The test statistic Z_{BE} is defined as follows

$$Z_{BE} = \frac{\sum_i m_i \sqrt{t_i}\, Z_i}{\sqrt{m_i^2 t_i}} \tag{16}$$

Where the m-values are computed by $m_i = P(T_i|\alpha_i) = \frac{P(\alpha_i|T_i = 1)\times P(T_i=1)}{P(\alpha_i|T_i = 0)\times P(T_i=0)+P(\alpha_i|T_i = 1)\times P(T_i=1)}$.

T_i is a random variable that has a value of 1 if study i has an effect, and 0, otherwise ($T_i = 0$), the prior probability of each study having an effect, is assumed to have a beta prior. The Markov Chain Monte Carlo (MCMC) was proposed to estimate the m-values [12]. The weight is approximated by $\sqrt{t_i} \cong \sqrt{n_i p_i (1-p_i)}$ where n_i is the sample size and p_i is the minor allele frequency (MAF) for the i^{th} study. Although this method has been found useful to detect associations showing heterogeneity, and to predict whether studies have an effect or not, this method does not differentiate the true heterogeneity and the statistical heterogeneity [12].

1.5 Meta-Regression

Meta-regression is an approach which ascertains the relationship of multiple predictors on effect magnitude [14]. Once possible confounders among covariates have been explored in the literature, meta-regression can be used to relate effect size with the other set of variables in the effect size model. Meta-regression can be carried out both under FEM and REM. Supposing that the underlying effect in the fixed or random-effects meta-regression are normally distributed in a linear predictor, meaning $\theta_1,\theta_2,\theta_3,\ldots,\theta_i \sim N(x_i\beta,\tau^2)$ the underlying effect of i^{th} study in a meta-regression, with s studies in denoted by

$$y_i \sim N\left(x_i\beta, \tau^2 + \sigma_i^2\right) \tag{17}$$

Equivalent to

$$y_i = x_i\beta + \varepsilon_i + \gamma_i \tag{18}$$

Where $\varepsilon_i \sim N\left(0, \sigma_i^2\right)$ and $\gamma_i \sim N(0, \tau^2)$ wherein y_i is the underlying effect for the i^{th} study (i = 1,...,s), β is a l x 1 vector matrix of coefficient which may cover a constant if well fitted, x_i is a 1 x l vector matrix of coefficient of covariates values in the i^{th} study with component values fixed between either 0 or 1, τ^2 the amount of heterogeneity, σ_i^2 the sampling variance for the i^{th} study, $_i$ the error of the sampling variance to the underlying effect in the i^{th} study and γ_i the error of the between-study variance to the underlying effect in the i^{th} study. Fixed effects or random effects meta-regression are considered as the extension of fixed effect or random effects meta-analysis and therefore are subjected to the assumptions of FEM and REM, described in the previous section. Meta-regression, when conducted under the REM explores the contribution of known covariates to heterogeneity while accounting for the residual variability that could not be explained by covariates incorporated in the meta-regression model [14]. In principle, study indicators in the meta-regression should be investigated following the outcome of the study design features and biological factors likely to bring about variability of observed study effects,

this lessens the burden of multiple testing and the potential for false positives arising from data cleaning. The power of the significant relationship between outcome variables and the multiple explanatory variables depends on the number of studies included in the meta-regression [15]. The coefficients in the meta-regression represent the change in the outcome variable per unit of increase in the predictor variables. The amount of heterogeneity in a meta-regression explained by the study indicators of interest with no covariates are compared with those in the models with covariates. The proportion of heterogeneity because of the predictor variables, denoted R_{adj}^2, is given by

$$R_{adj}^2 = \frac{\tau^2 - \tau_0^2}{\tau_0^2} \tag{19}$$

Where τ^2 and τ_0^2 are, respectively, the estimate of the amount of heterogeneity with covariate and without covariates. This indicator is often positive, except in the context of few studies and when the predictors in the meta-regression model explain less heterogeneity than would be expected by chance [15].

1.6 Genetic Effect with Trans-ethnic Meta-analysis Framework

The problem of trans-ethnic GWMA came about from the motivation that most of the SNP-specific GWMA was primarily carried out using GWAS summary statistics from studies of populations of European descent [16]. With GWAS data being increasingly accessible from diverse populations, transethnic meta-analysis is becoming an efficient approach to increase power to locate additional novel loci with associated effects. The trans-ethnic meta-analysis methodology includes more diverse populations and provides considerable performance improvements to detect associations and identify causal variants compared to fixed-effects meta-analysis. Additionally, this approach has increased power compared to random-effect meta-analysis with a well-captured similarity of allelic effects between populations [2, 16]. Morris (2011) proposed a Bayesian framework under the label "MANTRA" (Meta-Analysis of Trans-ethnic Association studies), which accounts for the relatedness by grouping studies (or ethnic groups) with the same underlying genetic effect into the same cluster and those with markedly different genetic backgrounds into different clusters [16]. Morris introduced the Bayesian partition model assuming that similar studies are more likely to have similar effect sizes, while dissimilar studies may have more variable effect estimates [16]. If we consider the different sets of clusters as one, all the separate individual studies can be aggregated into one with unvaried genetic effect sizes. In this instance, MANTRA becomes a Bayesian application of the fixed-effects technique. In case the number of clusters is equivalent to the number of studies, we correspond each study to its very own cluster, and MANTRA becomes the application of the Bayesian random-effects technique. Let b and s be, respectively, the observed allelic effect and the standard error under the null hypothesis, H_0 (no association of a variant with a trait in any population, $\beta = 0$), and the alternative hypothesis, H_1($\beta \neq 0$). The evidence of statistical association is assayed by the Bayes's Factor (BF) as follows

$$\Delta = \frac{f(b, s|H_1)}{f(b, s|H_0)} \tag{20}$$

The marginal likelihood of the observed allelic effect under model M is given by an integration over an unknown parameter x which includes the population specific allelic effects, β, and additional parameters related to their prior distribution (**Equation 21**). The model, M, varies according to the pattern of the population-specific allelic effects with different clusters.

$$f(b, s|M) \propto \int f(b, s|x) f(x|M) dx \tag{21}$$

The integration in **Equation 21** includes study-specific true allelic effect β_k and additional parameters relating to the prior distribution with likelihood $f(b,s|x) = f(b,s|\beta) = \prod_{k=1}^{N} f(b_k, s_k|\beta_k)$ and $f(b_k, s_k|\beta_k) \propto \frac{1}{s_k} \exp\left(\frac{(b_k-\beta_k)^2}{2s_k^2}\right)$. The likelihood function $f(b,s|M)$ is often computationally approximated using the Metropolis-Hastings MCMC algorithm as it cannot be directly evaluated analytically. MANTRA has proven to perform well in terms of increasing power to detect association compared to traditional fixed-effect and random-effect meta-analysis, shedding light on the heterogeneity of allelic effect between populations at particular loci, and enabling the detection of novel loci associated with complex traits in trans-ethnic GWAS [16]. Additionally, Shi and Lee proposed a novel REM for trans-ethnic meta-analysis, modelling the genetic effect heterogeneity across diverse populations [17]. This model, based on a kernel machine framework, assumes genetic distance to be the correlation structure across ancestral groups, with genetic effects taken as random variables. In addition, TransMeta achieves robust power using an adaptive variance component, regardless of the degree of genetic effect heterogeneity [17].

2. Some Aggregation Techniques for Gene-Specific GWMA

2.1 Gene-based Scoring using P-values.

The strategy applied using this approach consists of obtaining a regional or gene-based p-value from each study and then meta-analysing them. Different methods are being used to synthesize the association of SNPs within genes to address the association of the gene with the phenotype. Consider a set of m SNPs(m = 1,...,M) and their associated p-values p_m. Below we describe different methods enabling the combination of different p-values to generate a single statistic for the gene. The simplest proposed strategy is the Sidak's combination test, denoted by

$$P_{sidak} = 1 - (1 - err)^k \tag{22}$$

where err is the type I error rate and k is the number of independent SNPs [18]. We also denote the Fisher's combination test to combine k independent SNPs P-values are given by

$$P_{Fisher} = -2 \sum_{m=1}^{M} log(p_m) \tag{23}$$

where P_{Fisher} follows a chi-square distribution χ^2_{2m} with 2m degree of freedom. Alternatively, Stouffer's method makes use of the inverse normal distribution as below

$$P_{Stouffer} = \frac{1}{\sqrt{M}} \sum_{m=1}^{M} \Theta^{-1}(1 - p_m) \tag{24}$$

$P_{Stouffer}$ follows a normal distribution with mean 0 and variance $\sqrt{M}$ and Θ^{-1} is the inverse cumulative distribution function of the standard normal distribution [19]. In addition, the Simes combination test highlights how ranked p-values are combined using the statistic denoted by

$$P_{Simes} = min\left(\frac{mp_{(i)}}{i}\right) \tag{25}$$

where $p_{(i)}$ are the ordered p-values from the m SNPs p-values and P_{Simes} follow a uniform (0,1) distribution under the null hypothesis [20]. Such methods look agreeable in the absence of effect size estimates but are not widely implemented, since they have revealed a substantial loss of information, as it does not account for sample size and direction of effects[12]. Moreover, they model SNP effects as independent, which, as we now know, is inappropriate.

2.2 Gene-level meta-analysis based on score statistics.

The meta-analysis framework being used in this section can be decomposed on either a fixed-effect or random-effect approach. The overall approaches are either based on individual score test summary statistics issued from individual variant score tests, accompanied by an average variance-covariance matrix for the gene/region [27, 21, 22, 23, 24]. Others apply an aggregation test technique which encompasses effect and standard errors from the regression analyses followed by a correlation matrix of the individual variant [25]. Suppose that we have L independent studies. For k = 1,...,L, assuming that we have J variants in a gene or region of interest, let $S_{k,j}$ denote the score statistic for testing the null hypothesis of no association for variant j and $V_{k,j}$ its variance/covariance for the study k. The two major approaches for meta-analyses are the fixed effects and the random effects models.

FIXED EFFECT MODELS

Under the fixed effect models, the common effects of the j variants (j from 1 to J) across the k studies are assumed to be the same. We take the overall score statistic and the overall variance for each variant across the L studies denoted by [21, 27]

$$S_j = \sum_{k=1}^{L} S_{k,j} \quad and \quad V_j = \sum_{k=1}^{L} V_{k,j} \tag{26}$$

Under the null hypothesis, S(k) asymptotically follows a multivariate normal distribution with means 0 and variance V_j. In the case where the variant is not found in a specific study, the score and the variance are, respectively, equal to 0. Let's define $S = (S_1, S_2, \ldots, S_J)^T$ the gene score having the score for all the variants as components; and its variance $V = cov(S)$.

Under the additive mode of inheritance of continuous or binary traits, Tang and colleagues (2015) proposed the meta-analysis for the burden test statistics under the null hypothesis with no association formalized by:

$$T_{FE-Burden} = \frac{(\gamma^T S)^2}{\gamma^T V \gamma} \sim \chi_1^2 \tag{27}$$

Similarly, Liu [21] proposed another form of burden test:

$$T_{FE-Burden} = \frac{\gamma^T S}{\sqrt{\gamma^T S \gamma}} \sim N(0,1) \tag{28}$$

$\gamma = (\gamma_1, \gamma_2, \ldots, \gamma_J)^T$ is the vector weights mainly based on MAFs proposed by Madsen and Browning [26] $\gamma_j = \frac{1}{\sqrt{MAF_j(1-MAF_j)}}$. This weight has the advantage of being numerically stable and permits a normal approximation of the score statistic.

The Variant threshold (VT) test is obtained by computing the burden test statistics at each MAF below a certain threshold and minimizes the P-value over the observed MAF thresholds. Let τ the total number of MAFs threshold, and $T_{FE-Burden_l}$ the fixed effect burden test at the l^{th} threshold (l = 1...τ). The burden score at that threshold is given by $S_l = \gamma_l^T S$. Here γ_l is the vector of indicators where the a^{th} element equals 1 if the combined MAF at the variant site a is less than l and zero, otherwise. We can denote, by convenience, a matrix of indicators of the MAF threshold $\eta = (\gamma_{l_1}, \gamma_{l_2}, \ldots, \gamma_{l_n})$. Henceforth, the Variant threshold test statistic is indicated by

$$T_{FE-VT} = \max_{l=1\ldots\tau} T_{FE-Burden_l}, \qquad where \;\; T_{FE-Burden_l} = \frac{S_l}{\sqrt{\gamma_l^T S \gamma_l}} \tag{29}$$

The significance of the statistic is determined analytically using the cumulative distribution of the multivariate normal distribution S [21, 27]. More formally, given the covariance between test statistics computed from the alleles frequency thresholds, $(T_{FE-Burden_{l_1}}, T_{FE-Burden_{l_2}}, \ldots, T_{FE-Burden_{l_n}}) \sim MVN(0, \eta V \eta^T)$. Hence, the p-value of the Variant Threshold statistic is denoted by:

$$\begin{aligned} p-value &= 1 - \Pr(T_{FE-VT} \le t) \\ &= 1 - \Pr\left(T_{FE-Burden_{l_i}} \le t\right), i = 1, \ldots, n, \\ &= 1 - D_{MVN}(t, t, \ldots, t) \end{aligned} \tag{30}$$

where D_{MVN} is the multivariate normal distribution function with means 0 and variance $\eta V \eta^T$ [21, 27].

The meta-analysis framework for the Variant Component tests assumes that the mean effect of the variants in the gene/region is the same for each study. Assuming that the mean effect of the variants follows a multivariate normal distribution of m dimensional mean vector 0 and covariance matrix $\sigma_s W$, where σ_s refers to the variance component designating the variant effects within-study variation and $W = diag s_1^2, s_2^2, \ldots, s_J^2$ is a diagonal matrix in which s_j^2 denotes the within-study specified weight for the j^{th} variant (usually a function of the MAF). The meta-analysis score statistic for testing the null hypothesis that $\sigma_s = 0$ is given by[27, 28]:

$$T_{FE-SKAT} = S^T W S \tag{31}$$

For instance, if W is a diagonal $beta(MAF, v_1, v_2)$, the meta-analysis score statistic is equivalent to the SKAT statistic [68]. In the case when W is equal to the identity matrix, it generates the meta-analysis

for the C-alpha test [67]. The p-value of the test statistic from **equation 31** is determined by the mixture of the χ_1^2 $\sum_{j=1}^{J}$ $\alpha_j \chi_{1,j}^2$, where α_j is the j^{th} eigenvalue of $V^{\frac{1}{2}} W V^{\frac{1}{2}}$ and $\chi_{1,1}^2, \chi_{1,2}^2, \ldots, \chi_{1,J}^2$ are independent χ_1^2 random variables[27, 28]. SKAT-O[69], an extension of SKAT proposed an optimal test which consists of a linear combination of the SKAT and burden test under the form of a weighted sum of the squared score statistic [12, 28]. The meta-analysis formula is denoted by:

$$T_{FE-SKAT-O} = \rho T_{FE-burden} + (1-\rho) T_{FE-SKAT} \tag{32}$$

In practice, when ρ takes the value 1 (respectively 0), the test statistics correspond to the meta-analysis of the burden test (respectively of the SKAT statistic). The p-value is computed using a one-dimensional numerical integration and the value of ρ is chosen to minimize the p-value [28].

RANDOM EFFECT MODELS (REM)

Under REM, we assume the genetic effects of the different studies to be derived from the same distribution but are not the same. The biggest challenge is to quantify heterogeneity between and across studies, especially in the case of rare variants as they are population-specific [12]. The assumption behind the REM is expressed as [74]

$$\beta_k = \mu_* + \phi_k, k = 1, \ldots, K \tag{33}$$

where $\beta_k = (\beta_{k1}, \beta_{k2}, \ldots, \beta_{km})^T$ stands for the effects of the burden score on the k^{th} study, $\mu_* = (\mu_{1*}, \mu_{2*}, \ldots, \mu_{m*})^T$ represents the mean effect of the burden score across studies and $\phi_k = (\phi_{k1}, \phi_{k2}, \ldots, \phi_{km})^T$ the deviation of the effect of the k^{th} study from the mean μ_* assuming a multivariate normal distribution with mean 0 and covariance matrix σ(σ quantifies the between-study heterogeneity of the effects of the burden score). The meta-analysis burden test statistic assuming no effect($\mu_* = 0$) and no heterogeneity($\sigma = 0$)[28, 29] is given by:

$$T_{RE-Burden} = T_{FE-Burden} + \frac{(\sum_{k=1}^{K} S_k^2 - \sum_{k=1}^{K} V_k)^2}{2 \sum_{k=1}^{K} V_k^2} \tag{34}$$

The second term speaks of the score statistic for testing $\sigma = 0$ given $\mu_* = 0$. This statistic (**Equation 34**) measures the joint test of the mean and heterogeneity of the effects and attains high power under the condition of large mean effect size and/or robust between-study heterogeneity [28]. The Variant Threshold test under the REM is similar to the one from the FEM as denoted below:

$$T_{RE-VT} = \max_{l=1\ldots\tau} T_{RE-Burden_l} \tag{35}$$

where $T_{RE-Burden_l}$ is the meta-analysis random effect burden test statistic at the MAF threshold l and τ the number of thresholds)[28, 29]. Another proposed technique under the REM includes the Variant Component approach which incorporates the SKAT and SKAT-O tests. with individual genotypes of d-variants, we assume the following:

$$\beta_k^* = \mu + \phi_k^*, k = 1, \dots, K \tag{36}$$

where β_k^* denotes the value of the effect for the k^{th} study, μ refers to the average effects of all variants across the studies and ϕ_k^* the deviations of the effects from the k^{th} study from the average effect. Like in the FEM, we assumed that μ follow a J-variate normal distribution with mean vector 0 and covariance matrix $\sigma_s W$. In addition, ϕ_k^* follows a multivariate normal distribution with means vector 0 and covariance matrix $v_\delta \Delta$ where v_δ is a scalar which denotes the between-study variation of the effects and $\Delta = diag(\Delta_1^2, \Delta_2^2, \dots, \Delta_J^2)$ a diagonal matrix in which the Δ_i is regarded as the between-study weight of the j^{th} variant ($j = 1, \dots, J$) for the burden score effects. Lee and colleagues [22] proposed two test statistics accounting for heterogeneity. Het-SKAT tests the null hypothesis that $\sigma_s = 0$ and $v_\delta = 0$. Of the following, the RE models of SKAT test the joint null hypothesis that $v_\delta = 0$ and $\sigma_s = 0$, and its test statistic can be written as:

$$T_{RE-SKAT} = \begin{bmatrix} S_{\sigma_s} & S_{v_\delta} \end{bmatrix} V_\sigma^{-1} \begin{bmatrix} S_{\sigma_s} \\ S_{v_\delta} \end{bmatrix} \tag{37}$$

in which $S_{\sigma_s} = \frac{1}{2} T_{FE-SKAT} - \frac{1}{2} trace(VW)$, and $S_{v_\delta} = \frac{1}{2} T_{Het-SKAT} - \frac{1}{2} trace(VB)$ given the expression of Het-SKAT:

$$Het - SKAT = \sum_{k=1}^{L} S_{k,j}^T \Delta S_{k,j} \tag{38}$$

V_σ speaks of the covariance matrix of $(S_{\sigma_s}, S_{v_\delta})$ and is denoted by:

$$V_\sigma = \frac{1}{2} \begin{bmatrix} trace(VWVW) & trace\left(\sum_{k=1}^{L} V_{k,j} W V_{k,j} \Delta\right) \\ trace\left(\sum_{k=1}^{L} V_{k,j} \Delta V_{k,j} W\right) & trace\left(\sum_{k=1}^{L} V_{k,j} \Delta V_{k,j} \Delta\right) \end{bmatrix} \tag{39}$$

While Het-SKAT tests the heterogeneity at the variant level, $T_{RE-SKAT}$ tests both the heterogeneity and the means effect. As a result, Het-SKAT tends to be more powerful than $T_{RE-SKAT}$ in the presence of no effect, but the opposite happens in the presence of an effect [28, 22].

Another version of SKAT to test for heterogeneity effects called Het-SKAT-O was suggested as written below:

$$Het - SKAT - O = \rho\left(\sum_{j=1}^{J}\sum_{k=1}^{L}\Delta_j S_{k,j}\right)^2 + (1-\rho)Het - SKAT \tag{40}$$

ρ is adequately chosen between 0 and 1 to cause the most significant result. The level of significance of Het-SKAT and Het-SKAT-O can be estimated using modified moment-matching approximation and numerical integration [22]. For more accuracy, the Monte Carlo simulation is the best technique to quantify the p-values of the above tests. Lee and co-workers suggested simulating the sum of the score across all studies, applying the multivariate normal distribution and recomputing the test statistic. The p-value is defined as the proportion of the simulated test statistics that are more significant than the observed test statistics [22].

3 Some Aggregation Techniques for Pathway-based GWMA

3.1 Meta-analysis for Pathway Enrichment (MAPE)

The outline framework for MAPE is described below:

a. MAPE$_G$ Framework

MAPE$_G$ runs meta-analysis by synthesizing gene result statistics across studies and conducts pathway enrichment analysis just once using the combined gene results statistics [30, 31]. It generates the p-value statistic for each differential expression gene. Let t_{gk} ($1 \le g \le G$, $1 \le k \le K$) be the association score with the phenotype (supposed to be binary) for each gene g in study k obtained either by t-statistic or through a correlation measure, and I the indicator function. After permuting group labels B times, the permuted t-statistic t_{gk}^b($1 \le b \le B$) is used to estimate the p-value of the score p(t_{gk}) and the p-value of the permuted score p(t_{gk}^b) as defined below:

$$\begin{aligned} p(t_{gk}) &= \frac{\sum_{b=1}^{B}\sum_{g'=1}^{G} I\left(\left|t_{g'k}^b\right| \ge |t_{gk}|\right)}{B.G} \\ p(t_{gk}^b) &= \frac{\sum_{b'=1}^{B}\sum_{g'=1}^{G} I\left(\left|t_{g'k}^{b'}\right| \ge |t_{gk}^b|\right)}{B.G} \end{aligned} \tag{41}$$

Meta-analysis of all genes across all datasets is applied using the maximum p-value (maxP) statistic for the association score $u_g = \max_{1\le k\le K} p(t_{gk})$ and the permuted ones $u_g^b = \max_{1\le k\le K} p(t_{gk}^b)$. The p-value of the statistic maxP is estimated by $p(u_g) = \frac{\sum_{b=1}^{B}\sum_{g'=1}^{G} I(u_{g'}^b \le u_g)}{B.G}$. Given a pathway P, enrichment analysis is performed using the Kolmogorov-Smirnov (KS) statistic for gene set enrichment on $p(u_g)$ and $p(u_g^b)$ labelled, respectively, v_p and v_p^b. P-values and pathway p-values adjusted for false discovery rate(Q-value) are estimated for each pathway via permutation test as indicated below:

$$p(\nu_p) = \frac{\sum_{b=1}^{B} \sum_{p'=1}^{P} I\left(\nu_{p'}^{b} \geq \nu_p\right)}{B.P}$$
$$p(\nu_p^b) = \frac{\sum_{b'=1}^{B} \sum_{p'=1}^{P} I\left(\nu_{p'}^{b'} \geq \nu_p^b\right)}{B.P} \quad (42)$$
$$q(\nu_p) = \widehat{\theta_0} \frac{\sum_{b=1}^{B} \sum_{p'=1}^{P} I\left(\nu_{p'}^{b} \leq \nu_p\right)}{B.\sum_{p'=1}^{P} I(\nu_{p'} \leq \nu_p)}$$

where θ_0 is an estimate of the proportion of non-enriched pathways. The significance of the enriched pathway generated by $MAPE_G$ is given by

$$P_{MAPE_G} = \{p: q(\nu_p) \leq 0.05\} \quad (43)$$

Storey (2002) proposed an estimate of that proportion by $\theta_0 = \frac{\sum_{p=1}^{P} I(p(\nu_p) \in A)}{P.l(A)}$ where A is the closed interval $A = [0.5,1]$ and l(A) = 0.5[33]. The value θ_0 set to 1 have been recommended as numerous reports have mentioned challenges in estimating θ_0 for the reason that a poor estimate of θ_0 may deteriorate the FDR computation [30].

b. MAPEP Framework

In this framework, pathway enrichment analysis is conducted for each study, then combined using a maximum p-value approach to obtain the gross gene-set statistics. For each study k, we compute the p-value $p(t_{gk})$ for the gene g ($1 \leq g \leq G$)using Student-test; the KS approach is performed in any given pathway, P, for enrichment analysis to generate its score, ν_{pk}, and its significance, $p(\nu_{pk})$, as well as the ones after permutation B times ν_{pk}^b $p(\nu_{pk}^b)$ (**Equation 44**).

$$p(\nu_{pk}) = \frac{\sum_{b=1}^{B} \sum_{p'=1}^{P} I\left(\nu_{p'k}^{b} \geq \nu_{pk}\right)}{B.P}$$
$$p(\nu_{pk}^b) = \frac{\sum_{b'=1}^{B} \sum_{p'=1}^{P} I\left(\nu_{p'k}^{b'} \geq \nu_{pk}^b\right)}{B.P} \quad (44)$$

Meta-analysis is performed using maxP for all pathways across all data sets. The estimate of the p-values is given by:

$$p(w_p) = \frac{\sum_{b=1}^{B} \sum_{p'=1}^{P} I\left(w_{p'}^{b} \leq w_p\right)}{B.P}$$
$$p(w_p^b) = \frac{\sum_{b'=1}^{B} \sum_{p'=1}^{P} I\left(w_{p'}^{b'} \leq w_p^b\right)}{B.P} \quad (45)$$

where $p(w_p) = \max_{1\le k\le K} p(v_{pk})$ and $p(w_p^b) = \max_{1\le k\le K} p(v_{pk}^b)$. Q-value estimates via permutation tests, as well as the enriched pathways generated by $MAPE_P$ are computed as indicated below:

$$\begin{aligned} q(w_p) &= \frac{\sum_{b=1}^{B}\sum_{p'=1}^{P} I\left\{w_{p'}^b \le w_p\right\}}{B\sum_{p'=1}^{P} I\{w_{p'} \le w_p\}} \\ P_{MAPE_P} &= \{p: q(w_p) \le 0.05\} \end{aligned} \tag{46}$$

c. MAPE$_I$ Framework

$MAPE_I$ combines the results of $MAPE_G$ and $MAPE_P$ and computes p-value and FDR through permutation tests. More formally, let $s_p = min\{p(v_p), p(w_p)\}$ and $s_p^b = \min\{p(v_p^b), p(w_p^b)\}$ obtained from the $MAPE_G$ and $MAPE_P$ frameworks, the estimate of the p-value $p(s_p)$ is given by

$$p(s_p) = \frac{\sum_{b=1}^{B}\sum_{p'=1}^{P} I\left\{s_{p'}^b \le s_p\right\}}{B.P} \tag{47}$$

The Q-value of the integrated pathway as well as its significance are given below:

$$\begin{aligned} q(s_p) &= d\frac{\sum_{b=1}^{B}\sum_{p'=1}^{P} I\left\{s_{p'}^b \le s_p\right\}}{B\sum_{p'=1}^{P} I\{s_{p'} \le s_p\}} \\ P_{MAPE_I} &= \{p: q(s_p) \le 0.05\} \end{aligned} \tag{48}$$

Shen and Tseng (2010) made an important foundational effort in developing meta-analysis for pathway enrichment. This model holds promise in exploring power increase in pathway association; however, MAPE methods may be subject to power loss, as they do not account for different set sizes in their permutation-based procedures, and fall short of clearly managing between-study heterogeneity. All these limitations affect the performance of MAPE methods and has led several scholars to develop alternative tools to overcome these shortcomings [32].

3.2 Integrated Bayesian model for meta-analysis of gene set enrichment

Chen and colleagues (2013), proposed an integrated Bayesian framework which models gene expression data from multiple studies and gene set information, and performs differential expression analysis, together with gene set enrichment analysis and meta-analysis [31]. Unlike MAPE, which make use of a sequential approach, Chen and co-workers proposed a Bayesian inference model which jointly models gene set information and expression data from multiple studies and exhibits between-study heterogeneities for gene expression data by including non-overlapping genes [31].

Suppose we have J total number of distinct genes appearing in at least one of the K independent studies considered for meta-analysis so that for each study k($1 \le k \le K$), we have I_k samples. Let V_{jk} be the indicator variable for gene j($1 \le j \le J$) being included in study k. Granted V_{jk} = 1, let Y_{ijk} the expression intensity for gene j in sample i included in study k with i ∈ 1....I_k. For the purpose of

including different potential studies in meta-analysis, the model acknowledges different genes from the same genome to be found in different studies and subsequently assumes that a gene will always be differentially (equally) expressed with its expression differing across studies [31]. The mean expression intensity for a gene can be different in different studies, but here, we assume common mean intensity and common variance measurement errors among all samples of each phenotype in a study, *k*. Additionally, we define an indicator variable of a binary phenotype for study k given to sample i as:

$$X_{ik} = \begin{cases} 1\ if\ a\ case\ sample\ is\ in\ study\ k \\ 0\ if\ a\ control\ sample\ is\ in\ study\ k \end{cases} \tag{49}$$

The model mentioned that the expression intensity Y_{ijk} follows a normal distribution as denoted by $Y_{ijk}|V_{jk} = 1, \alpha_{jk}, \beta_{jk}, X_{ik}, \sigma_k^2 \sim N(\alpha_{jk} + \beta_{jk}X_{ik}, \sigma_k)$ where α_{jk} is the mean expression intensity for the control sample of gene j in study k; β_{jk} is the the change in expression intensity between the different phenotypes; and σ_k^2 the common variance measurement error assumed for all genes in study *k*. The model considers the expression of a gene, j, to be either equally expressed (EE), up-regulated (UR),or down-regulated (DR). Due to a change in expression intensity between different phenotypes, let's define the status of a gene, j, by a 3 dimension indicator vectors $n_j = (n_{jd})_{d\in 0,+,-} = (n_{j0}, n_{j+}, n_{j-})$ whereby n_{jd} = 1 represents a gene, j, is either EE(d = 0), UR(d = +) or DR(d = -) and 0, otherwise. This gives, by expansion

$$n_j = \begin{cases} (0,0,1)\ if\ gene\ j\ is\ DR \\ (0,1,0) if\ gene\ j\ is\ UR \\ (1,0,0)\ if\ gene\ j\ is\ EE \end{cases} \tag{50}$$

Due to the influence of the gene status in the expression change β_{jk}, we assume that β_{jk} follows a three modes mixture normal distribution with mean b_{kd} and variance τ_{kd}^2 as given by,

$$\beta_{jk}|n_{jd} = 1 \sim N(b_{kd}, \tau_{kd}^2) \tag{51}$$

where $d \in \{0, +, -\}$ represents the gene j's status with $b_{k0} \equiv 0$ and $b_{k-} < 0 < b_{k+}$. The model also assumes that $\alpha_{jk} \sim N(a_k, \tau_k^2)$. The indicator vector $(n_{jd})_{d\in\{0,+,-\}}$ is assumed to follow a multinomial distribution with the parameter vector defined by

$$(n_{jd})_{d\in\{0,+,-\}} \sim Mutinom\left(1, \left(\sigma_{d_{d\in\{0,+,-\}}}\right)\right) \tag{52}$$

where $\left(\sigma_{d_{d\in\{0,+,-\}}}\right) = (\sigma_0, \sigma_+, \sigma_-)$ denote the probability of EE, UR and DR genes, respectively, in the overall gene list.

Concerning the prior, the model emphasizes distributions on $\sigma \sim Dirichlet(1,1,1)$, $b_{k+} \sim Unif(0, D)$, $b_{k-} \sim Unif(-D, 0)$, and $a_k \sim Unif(-L, L)$ in which D represents the maximum absolute value of changes in gene expression in all K studies between different phenotypes, and L denotes the maximum absolute value of gene expression with phenotype, 0, in all *K* studies. The variance is assumed to follow an Inverse-Gamma distribution prior with shape, w, and scale, *v*. The values of *w* and *v* are taken at a small scale to allow density to reflect prior knowledge in variance parameters.

The gene set information is modelled as follows: let G be the total number of gene sets in which Z denotes the list of all the predefined gene sets examined in the meta-analysis. The elements of the matrix $Z * J$ being binary, set $Z_{gj} = 1$ if gene j is in set g and $Z_{gj} = 0$, otherwise. We denote the conditional probability that a gene is in set g given that the gene status is d ($d \in \{0, +, -\}$) by $\theta_{jd} = Pr(Z_{jd} = 1 | n_{jd} = 1)$. If for a particular gene set g, $\theta_{j0} = \theta_{j+} = \theta_{j-}$, then Z_{gj} is independent of n_j regardless the gene's status. However, that condition may not hold for all the G gene sets as some gene sets are likely to be co-expressed leading to positive correlation in their expression levels and also, the gene expression and the list of all gene sets depends on the gene status. Thereafter, the model assigns a beta prior to θ_{jd} for all $d \in \{0, +, -\}$ and $g \in \{1, \dots, G\}$ whereby $\theta_{jd} \overset{iid}{\sim} Beta\left(\sigma_d^* n_g, \sigma_d^*(J - n_g)\right)$. n_g is the number of genes in the gene set g and σ_d^* is the true proportion of genes with status d in the overall gene list. σ_d^* can be estimated from the gene expression data using existing methods, or be set to (1/3, 1/3, 1/3) to reflect prior belief, or defined via existing biological knowledge. According to the distribution of θ_{jd}, the mean is set to $\frac{n_g}{J}$ which shows that the mean probability for a gene belonging to set g is proportional to the size of the gene set, n_g , and does not depend on the gene status. The prior variance of θ_{jd} is given by $Var(\theta_{jd}) = \frac{\frac{n_g}{J}\left(1 - \frac{n_g}{J}\right)}{\sigma_d^* J}$. In practice, most genes are EE, this leads the model to employ few genes to allow a more concentrated set of EE genes around the prior mean, n_g/J , for set g. Meanwhile, θ_{g+} and θ_{g-} for DE genes have a large prior variability around the mean [31].

With regard to the posterior computation, the aim is to identify gene set enrichment. All the parameters involved have known distributions. The enrichment scores for the enriched gene sets can then be determined by evaluating the resulting joint model using a MCMC approach, selecting random samples from the joint distribution. Let ψ_{gd} be the conditional probability that a gene in a set g has status, d. According to [31], the enrichment of a gene in a set, g, is attained if $\psi_{g+} + \psi_{g-} > \sigma_+ + \sigma_-$. Denote $\phi_g \equiv Pr(\psi_{g+} + \psi_{g-} > \sigma_+ + \sigma_- | D)$ the posterior probability that set g is enriched given the observed data, D. By iterating over gene set g, let $\sigma_d^{(t)}$ and $\theta_{gd}^{(t)}$ the posterior draw from the parameters σ_d and θ_{gd} in the t^{th} iteration. The estimate $\widehat{\phi_g}$ of ϕ_g is given by

$$\widehat{\phi_g} = \frac{\sum_{t=1}^{T} I\left\{\psi_{g+}^{(t)} + \psi_{g-}^{(t)} > \sigma_+^{(t)} + \sigma_-^{(t)}\right\}}{T} \tag{53}$$

where T denotes the total number of iterations after the burn-in period and I the indicator function[31]. $\psi_{g+}^{(t)}$ and $\psi_{g-}^{(t)}$ are computed based on the Bayes rule:

$$\psi_{gd}^{(t)} = \frac{\theta_{gd}^{(t)} \sigma_d^{(t)}}{\sum_{d \in \{0,+,-\}} \theta_{gd}^{(t)} \sigma_d^{(t)}} \tag{54}$$

Enriched gene sets are identified by classifying all the gene sets based on $\widehat{\phi_g}$ and selecting the sets across the ranking list [31]. The model makes use of the Bayesian False Discovery rate (FDR) to choose the significance cut-off c for the enriched gene sets:

$$\widehat{FDR}(c) = \frac{\sum_{g=1}^{G}\left(1-\widehat{\phi_g}\right)I\{\widehat{\phi_g} \geq c\}}{\sum_{g=1}^{G} I\{\widehat{\phi_g} \geq c\}} \tag{55}$$

The choice of c is so that $\widehat{FDR}_{+}(c) \leq \nu$ where ν can take values 1, 5, or 10%.

One of the advantages of this approach is the integration of all the parameters in the model to perform pathway/gene set meta-analysis in parallel rather than in a sequential manner. Despite great human efforts to locate the convergence of MCMC in the model, the use of the classification strategy makes the results relatively easy to interpret [31]. However, the model is limited to binary phenotypes making it difficult to perform gene set enrichment for complex traits.

3.3 Integrative Gene Set Enrichment Analysis (iGSEA)

In the perspective of improving the gene set meta-analysis using gene expression statistics, Lu and colleagues proposed a method which integrates multiple independent gene-set enrichment studies sharing a common phenotype. This method allows the possibility to choose either a Fixed Effect or Random Effect meta-analysis approach, and applies to both discrete and continuous phenotypes [32]. The algorithm process includes the computation of the gene level statistics for each study taking information from the gene expression level data, followed by the overall computation of the gene level meta-analysis based on score statistic [27, 29] to address between-study heterogeneity, and finally, using an appropriate database of gene sets, ascertain enrichment of the identified gene sets [32]. To materialize these steps, let's define K-independent gene sets enrichment analysis sharing the same phenotype, giving rise to G genes within the genome in at least one of the K studies. The relationship between the expression level of gene g($1 \leq k \leq K$) in sample, j ($1 \leq j \leq J_k$) to the phenotype in study k with sample size J_k is modelled using the General Linear Model (GLM) to generate information which includes the effect of the gene, g's, and expression on the phenotype in the study, k. Let's denote the score statistic, U_{gk} , and its corresponding variance V_{gk} , obtained after testing the hypothesis for association with effect, β_{gk}, of gene, g, based on the distribution of the phenotype in the study, k. To aggregate gene expression data from multiple GSEA studies and test the overall association between the gene *g's* expression and the phenotype, the model considers three testing approaches:

a. Fixed Effect

This approach assumes homogeneity of gene expression effect between GSEA studies as clarified by:

$$\beta_{gk} \equiv \mu_g \quad for \quad k = 1, \vdots \ldots, K, \tag{56}$$

where μ_g denote the common effect of gene expression g among the studies. To test the hypothesis of no association of the common effect, the model makes use of the following overall statistic,

$$C_g^{FE} = \frac{\left(\sum_{k=1}^{K} T_{gk}U_{gk}\right)^2}{\sum_{k=1}^{K} T_{gk}V_{gk}} \tag{57}$$

where T_{gk} denotes the indicator function, equal to 1, in case gene, g, belonging to study, k, and 0, otherwise. Under the null hypothesis, $C_g^{FE} \sim \chi_1^2$. This statistic will be used at the latter stage when the gene set will be tested by ordering the C_g^{FE} values to indicate evidence of gene set association [31].

b. Random Effect and Between-Study Heterogeneity

To account for between-study heterogeneity, the REM is used to synthesize results for different studies as denoted below,

$$\beta_{gk} = \mu_g + \epsilon_{gk}, k = 1, \vdots \ldots, K, \tag{58}$$

where μ_g is the average genetic effect among studies and, ϵ_{gk} , the study-specific deviation of the effect from the mean effect, μ_g , assuming, the normal distribution, with mean 0 and variance, τ_g. In the presence of heterogeneity, the REM reach higher power compared to the FEM [12]. In this case, we test the null hypothesis H_0: $\mu_g = 0$ and $\tau_g = 0$, the overall test statistic is defined by

$$C_g^{RE} = \frac{(\sum_{k=1}^{K} T_{gk}U_{gk})^2}{\sum_{k=1}^{K} T_{gk}V_{gk}} + \frac{(\sum_{k=1}^{K} (T_{gk}U_{gk})^2 - \sum_{k=1}^{K} T_{gk}V_{gk})^2}{2\sum_{k=1}^{K} (T_{gk}V_{gk})^2} \tag{59}$$

The statistic C_g^{FE} is the first term of the above expression to test the null hypothesis with no effect under the FE model ($\tau_g = 0$). As for the FE models C_g^{RE} will be used at the latter stage when the gene set will be tested by ordering the C_g^{RE} values. Under the REM, Lu and colleagues proposed the use of the Q statistic to test the heterogeneity of gene, g, as denoted below,

$$Q_g = \sum_{k=1}^{K} T_{gk} w_{gk} (\hat{\beta}_{gk} - \hat{\beta}_g)^2 \tag{60}$$

wherein $\hat{\beta}_{gk}$ is the estimator of the effect β_{gk} and $w_{gk} \equiv \frac{1}{\sigma_{gk}^2}$ represents the gene's weight effect contribution in study k with σ_{gk}^2 the variance of the effect β_{gk}[32]. $\hat{\beta}_g$ denote the overall estimate of the weighted average effect of gene g across all studies defined by,

$$\hat{\beta}_g = \frac{\sum_{k=1}^{K} T_{gk} w_{gk} \hat{\beta}_{gk}}{\sum_{k=1}^{K} T_{gk} w_{gk}} \tag{61}$$

As we test the null hypothesis of no between-study heterogeneity, the Q_g statistic asymptotically follows a $\chi^2_{(\sum_{k=1}^{K} T_{gk} - 1)}$ distribution where the P-value can be derived. Alternatively, Lu and colleagues proposed the computation of the P-value based on permutation approaches using a list of methods which include the variance component type estimator (VC), the method of moments estimator (MM), the maximum

likelihood estimator (ML), the restricted maximum likelihood estimator (REML), the empirical Bayes estimator (EB), the model error variance type estimator (MV), a variation of the MV estimator (MVvc). Among these above-mentioned methods, MVvc and EB are found to be more performing in the case of large or moderate variance [32].

c. Adaptive testing

Besides the FE and RE testing, the model makes use of the adaptive approach for achieving robustness against model misspecification. The model tests the between-study heterogeneity under the RE model, $H_0^{(1)}: \tau_g = 0$. If $H_0^{(1)}$ is rejected, then the null hypothesis under RE model H_0 is also rejected confirming there exists at least one study whereby gene, g, is associated with the phenotype. On the other hand, $H_0^{(1)}$ not rejected, shift the test to the FE model with C_g^{FE} wherein $H_0^{(2)}: \mu_g = 0$. In addition, if $\sum_{k=1}^{K} T_{gk} = 1$; we shift the hypothesis testing to $H_0^{(2)}$. The overall P-value, denoted p_g^{AT} for each gene is obtained by combining the p-values of the two stages issued from the hypothesis $H_0^{(1)}$ and $H_0^{(2)}$. Let p_{1_g} and p_{2_g} the P-values of gene g in the respective stages 1 and 2 from the adaptive testing. As p_{2_g} is based on the FEM, the statistic C_g^{FE} follows asymptotically a χ_1^2 distribution. Then p_{2_g} can be determined either based on this distribution or via a standard permutation procedure. p_{1_g}, when testing $H_0^{(1)}$ correspond to the P-value while testing the null hypothesis of no variance. To determine the overall P-value of the adaptive test, denote α the overall significance level of the two-stage tests, and α_i the significance level for stage i(i=1, 2) such that $0 < \alpha_i < \alpha$. Let α_0 be the upper limit of α meaning $0 < \alpha < \alpha_0 \leq 1$. The following decision rule is applied to the model: (a) If $p_{1_g} \leq \alpha_1$, reject $H_0^{(1)}$; if $p_{1_g} > \alpha_0$, fail to reject $H_0^{(1)}$ and stop the test. (b) If $\alpha_1 < p_{1_g} \leq \alpha_0$, then proceed to the second stage. Assuming a predetermined function F(x,y), $H_0^{(2)}$ is rejected if and only if F(x,y) is less or equal to a function f determined by the condition

$$\alpha_1 + \int_{\alpha_1}^{\alpha_0} \int_0^1 IF(x,y) \leq f dy dx = \alpha \tag{62}$$

Wherein I is the indicator function. The model set $\alpha_0 = 1$ and the function $F(x,y) = p_{2_g}$. Then, the significance of our test is given by

$$p_g^{AT} = \begin{cases} p_{1_g} & if \quad p_{1_g} \leq \alpha_1 \\ \alpha_1 + p_{2_g}(1-\alpha_1) & otherwise \end{cases} \tag{63}$$

In the case of independence of the two stages, we have the equation $\alpha_1 + \alpha_2(1-\alpha_1) = \alpha$. The value of α_1 is set based on prior information about between-study heterogeneity or the common effect size [32]. In case, that information is not available, the model: either set $\alpha_1 = \alpha_2$ which entails $\alpha_1 = 1 - \sqrt{1-\alpha}$ or choose α_1 build on the exploration of data for assessing the heterogeneity [86]. To perform gene set enrichment analysis, let S be the number of gene sets to be tested and G_s the total number of

genes in a set s ($1 \leq s \leq S$). Let u_g the overall gene-level statistics obtained from either FE($u_g = C_g^{FE}$), RE($u_g = C_g^{RE}$) or AT($u_g = -p_g^{AT}$). The total number of genes, G, is ordered according to one of the three overall gene-level statistics as follows: For instance, if A and B indicate the statistic C_g^{RE} for genes in and out of gene s respectively, the order statistics are $A_{(1)}, A_{(2)}, \ldots, A_{(G_s)}$ and $B_{(1)}, B_{(2)}, \ldots, B_{(G_{-s})}$ wherein $G_{-s} \equiv G - G_s$. Let F_A and F_B respectively be the cumulative distribution function(CDF) for A and B. The hypothesis testing is formalized as follows

$$\begin{cases} H_0: F_A = F_B \quad for\ all\ x, \\ H_a: F_A \leq F_B \quad for\ all\ x\ and\ \ F_A < F_B \quad for\ some\ x \end{cases} \tag{64}$$

From the CDF F_A and F_B, we denote the respective empirical CDF $\hat{F}_A$ and $\hat{F}_B$ by,

$$\hat{F}_A(x) = \begin{cases} 0 & if\ \ x < A_{(1)} \\ \dfrac{m}{G_s} & if\ \ A_{(m)} \leq x < A_{(m+1)}\ \ for\ \ m = 1,2,\ldots,G_s - 1 \\ 1 & if\ \ x \geq A_{(G_s)} \end{cases} \tag{65}$$

$\hat{F}_B$ is defined similarly as $\hat{F}_A$.

Lu and colleagues consider a one-sided Kolmogorov-Smirnov(KS) test to ascertain whether the distribution of the overall gene-level statistic for genes in the set, s, is stochastically larger/smaller than the distribution of the same statistic for genes out of the set [32]. The enrichment score for a gene set, s, is given by,

$$v_s = \frac{h_s}{\sqrt{\dfrac{1}{G_s} + \dfrac{1}{G_{-s}}}} \tag{66}$$

where $h_s = \max_x\{\hat{F}_B(x) - \hat{F}_A(x)\}$ is the one-sided two-sample KS test statistic. v_s has an asymptotic distribution wherein the CDF is given by

$$F(y) = 1 - \exp(-2y^2), y > 0 \tag{67}$$

which does not depend on the size of the gene set [86]. After computing the enrichment score, the model randomly mixes up genes B times and assigns genes to the gene set to compute the permuted enrichment score, v_s^b , for all permutations, b($1 \leq b \leq B$). The model approximates the P-value of the observed score v_s as below,

$$p(v_s) = \frac{\sum_b^B I\left(v_s^b \geq v_s\right)}{B} \tag{68}$$

It is important to note that if one gene set is tested, the approach used for enrichment is to adopt an acceptable set-level statistic and compute its P-value through a permutation procedure. On the other hand, if more than one gene set is being tested, the model computes the Q-value as the minimum false discovery rate (FDR) to determine whether a set is truly statistically significant [32]. The Q-value of the observed v_s is given by,

$$q(v_s) = \frac{\hat{\pi}_0 \sum_{s'=1}^{S} \sum_{b=1}^{B} I\left(v_{s'}^b \geq v_s\right)}{B \sum_{s'=1}^{S} I(v_{s'} \geq v_s)} \tag{69}$$

Wherein $\hat{\pi}_0$ indicates the estimate of the proportion of non-enriched sets, and S is the number of gene sets being tested/determined using the method developed by Storey [32, 33], and implemented in the R package "qvalue". Gene sets with Q-value $q(v_s) < \sigma$ (σ = 0.05 by default in the model) is claimed to be enriched [32]. The model recommends the use of Adaptive testing in combining GSEA studies because of its performance in fitting multiple gene set sizes. However, the permutation procedure is much slower when the number of genes is larger [32]. The model is found to outperform the MAPE method [30] in terms of power and is able to adapt for covariates in the computational process. The method can extend its application to microarray analysis and NGS experiments in addition to other omics such as epigenomic studies in large consortia [32].

3.4 Meta-analysis-based Summary Adaptive Rank Truncated Product (SARTP)

The pathway-based meta-analysis methodology is summarized as follows: Assuming the availability of summary statistics including estimated effect size $\hat{\beta}_t^k$ and standard error τ_t^k for study $k(1 \leq k \leq N)$ at a particular SNP *t*, for each of the *k* participating studies, the fixed effects inverse-variance weighting method is being used to generate the combined effect size at each SNP *t*, as follows:

$$\hat{\beta}_t = \frac{\sum_{k=1}^{N} \frac{\hat{\beta}_t^k}{(\tau_t^k)^2}}{\sum_{k=1}^{N} \frac{1}{(\tau_t^k)^2}} \tag{70}$$

with its standard error denoted by

$$\tau_t = \frac{1}{\sqrt{\sum_{k=1}^{N} \frac{1}{(\tau_t^k)^2}}} \tag{71}$$

When only effect size and SNP p-values are at hand, the standard error can be computed as $\tau_t^k = |\hat{\beta}_t^k|/\sqrt{\chi^2_{1,p}}$, where χ^2_{1,p_t^k} denotes the quantile satisfy $P\left(\chi_1^2 \geq \chi^2_{1,p_t^k}\right) = p_t^k$ with χ_1^2 is the 1-df chi-square random variable [97]. Holding the condition that covariates and genotypes are uncorrelated or weakly correlated, added to large sample sizes, the model derives the approximated score statistic for each SNP, $S_t \approx \tau_t^{-2}\hat{\beta}_t$ and its variance-covariance matrix between two SNPs, *t* and *s*, denoted by

$$V_{ts} \approx \frac{n_{ts}}{\sqrt{n_t n_s}}\frac{\rho_{ts}}{\tau_t \tau_s} \tag{72}$$

whereby $n_t = \sum_{k=1}^{N} n_t^k$ and $n_{ts} = \sum_{k=1}^{N} n_{ts}^k$ n_t^k and n_{ts}^k denote, respectively, the number of samples that have their genotype available at SNP, t, and at both SNPs, *t* and *s*, for study, *k*. ρ_{ts} is the Pearson correlation coefficient between two SNPs, *t* and *s*, assuming being the same across all studies. The assumption regarding common correlation across studies holds if and only if either the sample source population is relatively homogeneous, or the subjects of the studies belong to the same ancestral population[35]. The correlation coefficient can be either estimated from one of the contributing studies or from publicly available databases, such as 1000 Genomes, HapMap, or NHLBI Exome Sequencing Project (ESP) [36, 37, 38]. To apply this approach, the model requires the SNP coverage information in each study as most often, sets of SNPs generated from GWAS can differ from one study to another [35]. In cases when the same set of SNPs are being used by all studies, then the variance-covariance matrix can be estimated without SNP coverage information. The next step is to aggregate the score statistics for pathway analysis. With the computed score matrix, $S = (S_t)_{q*1}$, and the variance-covariance matrix $V = (V_{ts})_{q*q}$, the model performs a pathway association test which is conducted using the framework of the Adaptive Rank Truncated Product (ARTP) [34, 35]. The framework includes the aggregation of P-values of SNPs to generate gene-based association statistics with associated significance levels, then combines the gene-level P-values into testing statistics for the pathway association. Formally, for each gene j with q_j distinct SNPs, we obtain their P-values as $p_{t_k} = P\left(\chi_1^2 \geq \frac{S_t^2}{V_{tt}}\right)$, for all k ∈ 1,...,$q_j$. We set the ordered statistic of those P-values by $p_{j_1} \leq p_{j_2} \leq \ldots \leq p_{j_{q_j}}$ For any predefined truncated integer point *K* and SNP-level cut points $c_1 < c_2 < \ldots < c_K$ such that the $p_{j_{c_k}}$s are part of the ordered statistics p-values. The negative log product statistics for that gene j at cut point c_K is given by

$$w_{jk} = -\sum_{t=1}^{\min(q_j, c_K)} \log\left(p_{j_t}\right), k = 1, \ldots, K \tag{73}$$

M copies of vectors of the score statistic S are sampled from the null distribution N(0,V) to be converted into a tail probability of χ_1^2 as $p_{t_1}^m, p_{t_2}^m, \ldots, p_{t_{q_j}}^m$, for $m \in 1, \ldots M$. These $p_{t_k}^m$ are used in the same manner to compute the negative log product w_{jk}^m for each copy m. The significance of w_{jk} is given by

$$\epsilon_{jk} = \frac{\#\{w_{jk}^m \geq w_{jk}; m = 1, \ldots, M\}}{M + 1} \tag{74}$$

To test the association between a gene j and the outcome, we set the ARTP statistic [34, 35] by $T_j = \min_{k=1,\ldots,K} \epsilon_{jk}$. Evaluating the significance can be computationally cumbersome. To avoid challenging resampling procedures, the significance of w_{jk} can be estimated by

$$\epsilon_{jk}^{m} = \frac{\#\left\{w_{jk}^{m'} \geq w_{jk}^{m}; m' \neq m, m = 1, \ldots, M\right\}}{M+1}, m = 1, \ldots, M \tag{75}$$

The estimated gene-level P-value of association between gene j and the outcome denoted T_j is calibrated by

$$P_{T_j} = \frac{\#\left\{T_j^{m} \leq T_j; m = 1, \ldots, M\right\}}{M+1}, j = 1, \ldots, J \tag{76}$$

where $T_j^{m} = \min_{k=1,\ldots,K} \epsilon_{jk}^{m}$. To compute the pathway-P-value, the method applies the same framework as above by combining gene-level P-values P_{T_j}[35]. For any predefined integer K' and gene-level cut points $d_1 < d_2 < \ldots < d_{K'}$, the ARTP statistic for pathway association is denoted by

$$T = \min_{k=1,\ldots,K'} \omega_k \tag{77}$$

where ω_k is the p-value of negative log product statistics defined on T_j, j = 1,...,J at a specific cut point d_k, k = 1,...,K'. The candidate genes involved in the secure pathway association signal are located at the top d_{k*} genes such that $\omega_{k*} = \min_{k=1,\ldots,K'} \omega_k$[34, 35]. Though the model provides possibilities to identify novel pathway signals that were undetectable due to the limitation of sample size, Zhang and colleagues mentioned the importance of SNP coverage information to accurately compute a variance-covariance matrix as most of the consortia do not provide this element. Zhang demonstrated that a lack of SNP coverage information may lead to an inflated false positive rate [35]. This method provides an avenue to extend the model accounting for LD structure in different ethnic populations[35].

3.5 Meta-analysis of Gene Set Analysis (META-GSA)

We describe below the summary workflow of META-GSA: Assume that we have S independent studies with SNPs GWAS summary information in which gene set analysis has been performed. For each SNP $m = 1, \ldots, M$ and for each study $s = 1, \ldots, S$ SNPs GWAS information includes: association measures(e.g. odd ratio) $\theta_{m,s}$,its corresponding P-value $p_{m,s}$ with test statistic $T_{m,s}$ from two-sided test hypothesis of no association $H_0: \theta_{m,s} = 1$ and alternative $H_A: \theta_{m,s} \neq 1$. The model assumes that gene set analysis based on the outcome of GWASs for each independent study s has already been carried out. The direction $d_{m,s}$ of the estimate $\theta_{m,s}$ is introduced by

$$d_{m,s} = \begin{cases} -1 \ \ if \ \theta_{m,s} < 1 \\ 1 \ \ if \ \theta_{m,s} \geq 1 \end{cases} \tag{78}$$

The above equation assumes that all representative markers are the same across the studies. If all significant markers assigned to gene, g, have the same direction, then $d_{g,s}$ which is the direction of gene, g, in the study, s, is the common direction of all significant markers assigned to that gene. Otherwise, the model accounts for the LD between significant markers from two different studies assigned to that gene by computing the mean correlation coefficient between the alleles of two significant markers within that gene. In such a case, the correlation between the alleles of two markers m_s and $m'_{s'}$ is being used to generate the gene-level direction by:

$$d_{g,s} = sign(\theta_{m,s}) r_{m_s, m'_{s'}} \tag{79}$$

From these above-mentioned estimates, markers are allocated to a gene, and the most significant marker in that gene is used to obtain the p-values of that gene within each study;

$$p_{g,s} = \min(p_{m|g,s}) \tag{80}$$

The direction of the gene depends on whether the direction of the markers assigned to that gene is the same or not. From there, we define the directed reversed p-value as

$$p'_{g,s} = d_{g,s}(1 - p_{g,s}) \tag{81}$$

The model also suggests the use of the weighted Fisher inverse χ^2-method for single marker p-values as a possibility to generate the gene-level statistic (**Equation 82**) and henceforth the p-value $p_{g,s}$ derived from the χ^2 distribution. The v_i are chosen as the inverse of the sum of the sum of r^2 across any pair of markers within the same LD block $\left(v_{m|g} = \frac{1}{\sum_{m'} r^2_{m'|g,m|g}}\right)$.

$$C_{g,s} = -2 \sum_{i=1}^{n_{m|g,s}} v_i \ln(p_{i,s}) \tag{82}$$

The degree of freedom of the χ^2 distribution is the sum of the marker weights $\sum_{g,s} v_{m|g,s}$ which is also equivalent to the number of independent markers. Provided with this information, the gene-level direction is given by the weighted mean of marker-specific direction using the same marker weight $v_{m|g,s}$:

$$d_{g,s} = \sum_{i=1}^{n_{m|g,s}} v_i sign(\theta_{i,s}) \tag{83}$$

and the p-value of the gene within each study is a function of all markers within the gene $p_{g,s} = f_{m|g}p_{m|g,s}$. The second step consists of computing the study weights from rank correlations of PDRs. To that end, the model uses the Kendall rank correlation coefficient as the pairwise correlation of observed PPDR profiles between studies to generate the correlation matrix [38]. Next, the model implements the principal component analysis (PCA) to generate the contribution of each study *s*, on the common PPDR profile of the gene set (though unknown) assuming that each contribution is represented by the first principal component ($PC1_s$). the generated eigenvalue, EV1, is S-times the fraction of the variance accounted for by $PC1_s$ through which we defined the "effective number of studies" by $\frac{EV1}{S}$. Hence, the study weight w_s is computed as the product between the number of the normalized contribution to the "effective number of studies" by:

$$w_s = \frac{PC1_s}{\sum_{j=1}^{S} PC1_j} . \frac{EV1}{S} \tag{84}$$

This indicator satisfies the sum of weights equal to the “effective number of studies” and not to 1 for the perspective to apply significance testing. The model proposes a permutation procedure; herein genes are allocated to gene sets to determine the weights which satisfy the conditions: $1 \geq w_s \geq 0$ for all s and $\sum_{s=1}^{S} w_s = 1$. Using these weights, we produce random p-values of gene sets from a uniform distribution [38]. The statistical significance by permutation denoted $p_{permuted,GS}$ is obtained by the fraction of permutations achieving a test statistic $M_j = -2\sum_{s=1}^{j} w_s \ln(p_{GS,s})$($j$ from 1 to x) [39, 38]. With $p_{GS,s}$ denoting the gene set significance for study s. $p_{permuted,GS}$-values might not be all independent due to the presence of a single gene in several gene sets or genes in LD between each other. Then, the model applies correction for multiple testing using the bootstrap approach developed by Storey and Tibshirani [40, 38] whereby the $p_{permuted,GS}$-values are being used to compute the tuning parameter, λ , and then generates the proportion of true null hypotheses π_0 by:

$$\pi_0(\lambda) = \frac{n_{GS} - n*_{GS}(\lambda) + z}{(1-\lambda)n_{GS}}, \qquad for\ \lambda \in K = \left\{0, \frac{1}{n_{GS}}, \dots, \frac{n_{GS}-1}{n_{GS}}\right\} \tag{85}$$

Where $n*_{GS}$ is the number of $p_{permuted,GS}$-values less or equal to λ, and z = 1 for the finite-sample case or takes the value, 0, otherwise. For each value of λ, the model bootstraps on the p-values to sort B bootstrap classes $\pi_0^b(\lambda)$ for $b = 1, \dots, B$ and choose the optimal value of λ that sort the minimum $\widehat{MSE}(\lambda) = \frac{1}{B}\sum_{b=1}^{B} (\pi_0^b(\lambda) - \min_{\lambda \in K}\pi_0(\lambda))^2$. As a result, the corrected p-value is determined by:

$$p_{META-GSA,GS} = \min\left(1, p_{permuted,GS}.n_{GS}.\pi_0(\lambda)\right) \tag{86}$$

META-GSA applies to any gene set analysis method, with the possibility of adding individual participants' genotype data, which seems more powerful than methods based on GWAS summary statistics. However, the model is limited by its reliance on SNP, gene and pathway annotations in databases, which are currently incomplete. Furthermore, the model generates p-values and does not provide effect estimation, hence reflecting incomplete activity information at the pathway/gene set level.
